with great biological, genetic, and cultural diversity. Their fairness depends in large part on the skills of the parties to negotiate adequate benefit-sharing and compensation provisions. In the past, negotiators from developing countries may not have been as qualified as their counterparts from industrialized countries, but this is changing. The actors involved in the business of bioprospecting have increased in diversity, number, and expertise. Information about the rights and obligations of bioprospecting parties and their collaborators has proliferated, and it is reaching scientists and indigenous groups from developing countries.

NONLEGALLY BINDING INSTRUMENTS: CODES OF CONDUCT

In the absence of clear access and benefit-sharing policies, codes of conduct have provided guidance to facilitate access to and exchange of genetic resources. In 1993, for example, the Commission on Plant Genetic Resources and the FAO conference adopted an International Code of Conduct for Plant Germplasm Collecting and Transfer as a voluntary instrument pending the adoption of the Treaty. The code also proposes minimum guidelines for sponsors, curators, collectors, and other users of genetic resources covering the collection and transfer of these resources.

In practice, it is often necessary to obtain access permits when collecting genetic resources in nature, but most samples are obtained by exchange among institutions. Many countries allow for relatively unrestricted access to their gene banks and encourage the use of MTAs to facilitate the exchange of germplasm. Under MTAs, germplasm can only be used for research purposes and they may oblige the recipient not to seek intellectual property protection over the material transferred or its derivatives. This contractual mechanism has been used by organizations worldwide to provide important benefits to the agriculture of many nations. Equally effective has been the “standard order form” used by the International Agriculture Research Centers (IARCs) for the transfer of “designated germplasm” from ex situ collections maintained in international centers before the CBD came into force. Under this form, participants agree not to seek intellectual property protection over germplasm transferred and to ensure that future recipients are bound by the same obligation.\[11\]

CONCLUSION

It has been more than 10 years since the signing of the CBD and no significant sharing of economic benefits has been documented from the use of genetic resources identified in this period. For example, the pharmaceutical industry has not developed any moneymaking drug from native genetic resources and has not been able to share with local communities the millions of dollars that analysts predicted in the 1980s and early 1990s. It is unlikely that such an amount of money will ever flow to local communities. However, some pharmaceutical companies have identified potentially useful chemical substances and molecular structures,\[10\] and since drug development usually takes between 10 and 15 years, there is still hope that some products will be developed in the near future. In the meantime, universities, pharmaceutical, and biotechnology companies continue to test many biological samples, most of them aware of the regulatory power of the CBD and national access laws that limit their access to new genetic resources, but not many have a good understanding of the scope of these laws. There is also great concern about the lack of clarity of government provisions to implement these access laws. In addition, many companies complain about high transaction costs, bureaucracy, and corruption. Representatives of the pharmaceutical, biotechnology, and seed industry also believe that this relatively new legal environment will force their organizations to stop collecting in nature. Instead, they will go back to ex situ conservation collections maintained in developed countries where access is free.\[11\] However, native germplasm of some taxa in such collections is quite limited in diversity and eventually a return to the natural environment for more samples will be necessary.

Scientists perceive that access laws have imposed barriers to academic, scientific, and commercial research.\[12\] Many developing countries lack the capacity and expertise to negotiate access contracts and prefer to close their borders to bioprospecting initiatives to keep the option of future value of species with potential medicinal and industrial applications. The International Center for Tropical Agriculture (CIAT), for example, has stopped collecting native germplasm in several Andean countries until existing access and benefit-sharing policies and procedures are clarified and streamlined. Other source countries such as Mexico face great pressure to restrict access from indigenous groups that oppose bioprospecting initiatives because of the lack of transparency of these initiatives.

Genetically Engineered Crops with Resistance Against Insects

Johnie N. Jenkins
USDA—ARS, Mississippi State, Mississippi, U.S.A.

INTRODUCTION

Many insect pests reduce yield and quality of agricultural crops, and a large worldwide market exists for insecticides for their control. Even though insecticides are used for their control, insects in the order Lepidoptera and Coleoptera remain major worldwide pests of important food and fiber crops. The common soil bacterium, *Bacillus thuringiensis* (Berliner), produces a crystalline protein that is toxic when consumed by certain larvae in those orders. Insecticides based on crystalline proteins from *B. thuringiensis* have been useful in the control of Lepidopterous caterpillars. These *B. thuringiensis* pesticides have been used successfully and safely for over 50 years. They are not toxic to humans, to other mammals, or to other higher animals.

Host plant resistance to insects has been developed for several crops using conventional breeding of genes within the plant species. Genetic transformation technology offers a means of moving genes across the species barrier. With the advent of this technology in the early 1980s, scientists began attempts to transform plants using genes from *B. thuringiensis*, thereby providing control of selected insects using a bacterial gene genetically engineered into a plant. The first reported use of a toxin gene from *B. thuringiensis* expressed in plants occurred in 1987 when tobacco plants, *Nicotianatabacum* L., were developed that produced enough of the toxin to kill first instar larvae of tobacco hornworm, *Manduca sexta* L., placed on leaves of transformed plants. Transgenic Bollgard cotton was first grown commercially in the United States in 1996. In 2000, cotton with a gene from *B. thuringiensis* was grown on 1.5 million hectares (ha) and cotton with this gene plus a herbicide resistance gene was grown on 1.7 million ha in the world, primarily in the United States, China, Australia, Argentina, Mexico, and South Africa. The United States is the largest user of Bollgard cotton with 39% of the U.S. crop in 2000 planted to Bollgard or Bollgard plus herbicide resistant cotton. In China, cotton with a *B. thuringiensis* gene was grown for the first time in 1997 on 63,000 ha and in 2000 it was grown on 500,000 ha. Monsanto was the first company to produce transformed cotton, corn, *Zea mays*, and potato, *Solanum tuberosum*, plants that expressed toxin(s) from *B. thuringiensis* at levels needed for commercial control of targeted insect pests. This increased toxin expression in transformed plants resulted from modifications by Monsanto scientists to the DNA sequence of a specific toxin gene of *B. thuringiensis*.

All the transgenic, insect-resistant crop species that have been commercialized to date express one of the various crystalline proteins from *B. thuringiensis*. Three transgenic crop species are currently approved by the U.S. Environmental Protection Agency (EPA) for growing in the United States. The Cry1Ac protein in cotton was registered by Monsanto as Bollgard and targeted to tobacco budworm, *Heliothis virescens* (Fab.), bollworm, *Helicoverpa zea* (Boddie), and pink bollworm, *Pectinophora gossypiella* (Saunders). The Cry3A protein in potato was registered by Monsanto as NewLeaf and targeted against the Colorado potato beetle, *Leptinotarsa decemlineata* Say. The Cry1Ab protein in corn was registered by Syngenta Seeds, Inc. as YieldGard for full commercial use in field corn. The Cry1Ab protein in corn was registered by Syngenta Seeds, Inc. as YieldGard and Attribute™ for full commercial use in field and sweet corn, respectively.

Transgenic Bollgard cotton was first grown commercially in the United States in 1996. In 2000, cotton with a gene from *B. thuringiensis* was grown on 1.5 million hectares (ha) and cotton with this gene plus a herbicide resistance gene was grown on 1.7 million ha in the world, primarily in the United States, China, Australia, Argentina, Mexico, and South Africa. The United States is the largest user of Bollgard cotton with 39% of the U.S. crop in 2000 planted to Bollgard or Bollgard plus herbicide resistant cotton. In China, cotton with a *B. thuringiensis* gene was grown for the first time in 1997 on 63,000 ha and in 2000 it was grown on 500,000 ha. In 2000, growers of Bollgard cotton accrued $168 million in economic benefit from lower production costs and increased yield. They applied 1.04 million fewer pounds

GENETICALLY ENGINEERED CROPS

Transformation of plants by the bacterium *Agrobacterium tumifaciens* became routine in the early 1980s. In 1987, cotton plants, *Gossypium hirsutum* L., were first regenerated from cells into complete plants via tissue culture. Scientists had previously attempted to transform cotton plants with DNA sequences of the delta endotoxin gene from *B. thuringiensis* var kurstaki. Scientists at Monsanto Co. first transformed tomato, *Lycopersicon esculentum*, to express the Bt toxin gene and field tested these plants. Scientists at Agracetus were the first to produce cotton plants for field testing that expressed the *B. thuringiensis* gene. However, when Agracetus cotton plants were grown in field plots they did not express the toxin at a level sufficient to control targeted insects. Monsanto was the first company to produce transformed cotton, corn, *Zea mays*, and potato, *Solanum tuberosum*, plants that expressed toxin(s) from *B. thuringiensis* at levels needed for commercial control of targeted insect pests. This increased toxin expression in transformed plants resulted from modifications by Monsanto scientists to the DNA sequence of a specific toxin gene of *B. thuringiensis*.

All the transgenic, insect-resistant crop species that have been commercialized to date express one of the various crystalline proteins from *B. thuringiensis*. Three transgenic crop species are currently approved by the U.S. Environmental Protection Agency (EPA) for growing in the United States. The Cry1Ac protein in cotton was registered by Monsanto as Bollgard and targeted to tobacco budworm, *Heliothis virescens* (Fab.), bollworm, *Helicoverpa zea* (Boddie), and pink bollworm, *Pectinophora gossypiella* (Saunders). The Cry1Ab protein in corn was registered by Syngenta Seeds, Inc. as YieldGard and Attribute™ for full commercial use in field and sweet corn, respectively.

Transgenic Bollgard cotton was first grown commercially in the United States in 1996. In 2000, cotton with a gene from *B. thuringiensis* was grown on 1.5 million hectares (ha) and cotton with this gene plus a herbicide resistance gene was grown on 1.7 million ha in the world, primarily in the United States, China, Australia, Argentina, Mexico, and South Africa. The United States is the largest user of Bollgard cotton with 39% of the U.S. crop in 2000 planted to Bollgard or Bollgard plus herbicide resistant cotton. In China, cotton with a *B. thuringiensis* gene was grown for the first time in 1997 on 63,000 ha and in 2000 it was grown on 500,000 ha. In 2000, growers of Bollgard cotton accrued $168 million in economic benefit from lower production costs and increased yield. They applied 1.04 million fewer pounds
of insecticide. Additional benefits were reduced pesticide exposure risks, improved preservation of beneficial insects, and increased wildlife benefits.[12] In China, the Chinese Academy of Agricultural Sciences (CAAS) and Monsanto/DeltaPine each have versions of Bt cotton grown by an estimated 3 million small farmers in 2000.[11] Transgenic Bt cotton offers the small farmers of China a significant increase in income and a significant decrease in pesticide usage and associated pesticide problems.

Corn is another major crop with a significant area planted to transgenic hybrids. Corn with a gene from \textit{B. thuringiensis} was first planted in the United States in 1996. In 2000, 6.8 million ha were planted on a global basis, with 92% planted in the United States.[11]

**HOW PLANTS WITH GENES FROM \textit{B. thuringiensis} KILL INSECTS**

The toxin produced by transgenic plants transformed to express the toxin gene from \textit{B. thuringiensis} affects susceptible insects as the protein[13] is solubilized and proteolytically processed into polypeptide molecules that bind with specific affinity to receptor sites in the insect’s midgut epithelial cells. This causes pores or ion channels to develop in the cell membranes, thus disturbing cellular osmotic balance and causing cells to swell and lyse and causing paralysis in the insect’s midgut and mandibles. Death then occurs through a combination of starvation and septicemia.

**MANAGING OR DELAYING DEVELOPMENT OF INSECT RESISTANCE TO Bt IN GM CROPS**

Management of the development of resistance to \textit{B. thuringiensis} insecticidal toxins in transgenic plants is of great concern to many people.[13] The U.S. EPA requires a unique resistance management plan as part of its approval of transgenic Bt cotton and corn. This resistance management plan requires delayed development of populations of pest insects that are resistant to the toxin. The plan was developed around a high-toxin dosage and a concept of refuge in which susceptible insects are produced in sufficient numbers to mate with the low numbers of resistant insects that may survive on the transgenic crops. Because no actual data had ever been developed to test this strategy, insect population models were developed and used to define refuge sizes and a strategy for use. General conclusions from population models were that 1) the level of toxic protein should be very high relative to the target pests LD90; 2) these crops should be planted in a manner that allows high levels of mating among susceptible and resistant pest insects; and 3) movement of larvae between transgenic and nontransgenic plants must be avoided.[14]

**CURRENT STATUS OF \textit{B. thuringiensis} GENES IN PLANTS**

Approximately 40 different insect resistance genes have been introduced into crop plants.[15] At least 10 Bt genes encoding different Bt toxins (cry1Aa, cry1Ab, cry1Ac, cry1Ba, cry1Ca, cry1H, cry2Aa, cry3A, cry6A, and cry9c) have been genetically engineered into 26 species of plants; however, codon-optimized genes have been transformed into only cotton, corn, potato, broccoli, \textit{Brassica oleracea italic}, cabbage, \textit{B. oleracea capitata}, and alfalfa, \textit{Medicago} sp.[15]

**CONCLUSION**

In the future many types of genes will be used to genetically engineer insect resistant plants. Some of the promising non-cry genes from \textit{B. thuringiensis} and \textit{B. cereus} are the vegetative phase insecticidal proteins VIP 1, VIP 2, and VIP 3A.[15] Candidate genes, other than those from \textit{B. thuringiensis}, are plant protease inhibitors, plant amylase inhibitors, plant lectins, and chitinases. From animals, serine protease inhibitors and chitinase genes are being investigated. At present, only plants with \textit{B. thuringiensis} cry genes have been commercialized.[15] Over 240 insecticidal cry proteins produced by the various strains of \textit{B. thuringiensis} have been classified.[16] In addition to these other genes, there seems to be ample genetic variability among \textit{B. thuringiensis} strains to allow scientists to use these cry genes to develop many different versions of crop resistance.

Genetically Modified Oil Crops

Denis J. Murphy
University of Glamorgan, Cardiff, U.K.

INTRODUCTION

For over five thousand years, oil crops have been sources of many useful nonfood products ranging from lubricants to lamp fuels. Since the late 19th century, such nonfood uses of plant oils have declined due to the twin pressures of relatively cheap petroleum-based alternatives and the need to feed the ever-increasing human population of our planet. By the late 20th century, less than 15% of plant-derived oils were used for industrial purposes. The vast bulk of vegetable oils are currently traded as commodities destined for human consumption in such products as margarines, cooking oils, and processed foods. More recently, however, interest has revived in the possible exploitation of oil crops for a wide spectrum of nonedible products including cosmetics, biodegradable plastics, and even high-value pharmaceuticals.

MARKETS AND CROPS

Global vegetable oil markets are dominated by the “big four” crops—soybean, oil palm, rapeseed, and sunflower—which together make up over 86% of the total global traded production of almost 90 million tonnes. The major aim of oil crop engineering has been to alter the fatty acid profiles of the major oil crops. As shown in Table 1, these crops have relatively narrow fatty acid profiles dominated by C16 and C18 groups that are not optimal for many industrial uses. On the other hand, there are many examples of minor crops and noncrop plants that accumulate very high levels of a diverse range of novel fatty acids with chain lengths from C8 to C24, and with useful chemical functionalities such as hydroxyl, epoxy, and acetylenic groups. Such oils can be used for the manufacture of products such as adhesives, paints, detergents, lubricants, and nylons, to name but a few. In Table 2, some examples of oil-bearing seeds that already produce some of these novel and potentially useful fatty acids are shown. Over the past decade, many of these plants have been used as sources of genes encoding fatty acid biosynthetic enzymes for transfer into mainstream oil crops in the hope that those crops would then accumulate the novel oils on a scale of up to millions of tonnes per year. This concept has been termed “designer oil crops.”

Rapeseed was successfully transformed as early as 1984, followed by sunflower and soybean in the 1990s. More recently, marker transgenes have been inserted into oil palm and lipid biosynthetic genes will doubtless soon follow, although it will probably be another decade before alteration of the oil composition of this important tree crop has been achieved. Most of the genes related to fatty acid biosynthesis were isolated during the 1990s, either from the various exotic oilseeds or from model plants such as Arabidopsis thaliana, which as well as being an important research plant is also an oilseed that accumulates storage lipid as almost half of its seed weight. Therefore, in principle, it should now be possible to engineer transgenic oil crops to produce the desired range of novel fatty acids for a variety of industrial applications.

PROBLEMS AND PROSPECTS

Unfortunately, it appears that the accumulation of high levels of a single desired fatty acid in the storage oil, although fairly common in nature, is not readily achievable by simply inserting a few lipid biosynthetic genes into a given transgenic plant. There is increasing evidence that fatty acid modifications may behave as quantitative traits that are controlled to a greater or lesser extent by numerous genes. It may be the case that in order to achieve levels of 90% of a particular fatty acid in a crop plant, the insertion of at least four and as many as ten transgenes may be required. This will add considerably to the cost and timescale of such manipulations.

Another problem in oil crops such as rapeseed is that exotic fatty acids designed for sequestration in the storage oils may sometimes also accumulate in membrane lipids, with possible deleterious consequences. Plants that naturally accumulate exotic fatty acids such as lauric acid (C12), which is a powerful membrane-destabilizing detergent, have evolved mechanisms to “channel” these deleterious fatty acids into the storage lipid pool. This mechanism, which probably involves specific phospholipases and acyltransferases, is found in lauric-accumulating seeds such as Cuphea spp and Umbellaria californica.
but does not appear to be particularly active in rapeseed.\textsuperscript{[4]} A further potential technical challenge to the engineering of designer oil crops is the finding that some of the gene promoters most commonly used to achieve the seed-specific expression of transgenes may also direct gene expression in other tissues, including roots.\textsuperscript{[5,6]} While it is possible that in many cases the accumulation of exotic fatty acids in nonseed tissues may not be problematic, this may not always be true, and it underlines the need for the thorough metabolic profiling of all transgenic varieties before their general release.

The consequence of these and other complexities of plant molecular genetics and metabolism is that, despite many impressive achievements in isolating oil-related genes and producing transgenic plants with modified seed oil compositions, it has not been possible yet to achieve the kind of high levels (80–90\%) of novel fatty acids that will make possible their widespread commercial exploitation. In the case of the high-lauric transgenic rapeseed (canola) crop, difficulties in its commercialization are also due to the existence of a competing source of lauric oil, namely palm kernel oil from the Far East. Palm oil is both cheaper to produce than rapeseed oil and in much more plentiful supply. The lauric-oil variety of rapeseed was improved from 40\% to 60\% lauric content by the insertion of several additional transgenes,\textsuperscript{[3]} but it still remains far from being a commercial success and is no longer under development as a crop variety in the United States.

The availability of many genes involved in fatty acid modification and the good progress in transforming the main oil crop species will doubtless encourage further efforts to resolve the challenge of low levels of novel fatty acid production. But even if such efforts are successful, the commercial success of transgenic oil crops will remain problematic. It will be necessary to identify and develop robust markets for transgenic oil products; simply substituting for low-cost petroleum-derived products may not always be true, and it underlines the need for the thorough metabolic profiling of all transgenic varieties before their general release.

such as adipic acid and vinyl chloride. Some soil bacteria such as *Ralstonia eutrophus* are able to accumulate up to 80% of their mass in the form of nontoxic biodegradable polymers called polyhydroxyalkanoates (PHAs). The PHAs are made up of β-hydroxyalkanoate subunits that are synthesized from acetyl-CoA via a relatively short pathway involving as few as three enzymes for the most common PHA, polyhydroxybutyrate. The cost of PHAs could be considerably reduced if they were produced on an agricultural scale in transgenic crops. This prospect has led several companies, including Monsanto and Metabolix, to attempt to develop transgenic rapeseed plants containing the bacterial genes responsible for PHA biosynthesis. Provided the PHAs accumulate in the plastids, and not in the cytosol, it is possible to obtain modest yields of the polymer from either leaves or seeds. A major and as yet unresolved technical hurdle is how to extract biopolymers from plant tissues in an efficient and cost-effective manner. Another complexity is that polyhydroxybutyrate, which is the most widespread PHA, is a rather brittle plastic and is not suitable for most applications. The best-performing plastics are copolymers of polyhydroxybutyrate with other PHAs, such as polyhydroxyvalerate. Although the production of such copolymers in transgenic plants is considerably more difficult than the production of single-subunit polymers, progress has recently been made in this area. While there are several companies and academic labs attempting to make commercially extractable PHAs in plants (including one in oil palm), it seems unlikely that these environmentally friendly products will be commercially available for quite a few years to come.

Apart from these scientific and technical challenges, engineered oil crops also face considerable challenges regarding their management and economics. The major managerial problem concerns the need to segregate a transgenic crop variety producing a novel product from nontransgenic commodity crops and from other transgenic varieties of the same species that accumulate different products. This is a formidable task, given the intricacy of the supply chain from breeder to grower to processor and so on, all the way to the retailer and, ultimately, to the consumer. The difficulties in ensuring strict segregation of otherwise indistinguishable transgenic crops have consistently been underestimated by many in the industry. Several well-publicized failures in the segregation of transgenic rapeseed and maize crops in recent years (e.g., the STARLink affair, although note that this did not involve genes modified for oil composition) have thrown this issue into much sharper focus. The contamination of a batch of seeds containing, for example, a hydroxy oil designed for industrial use with another batch of seeds containing a high-oleic oil for edible consumption (or vice versa) would result in a mixture that would be useless for both purposes. Efficient segregation is likely to be both difficult to control and expensive to implement. This may limit the cultivation of transgenic crops producing novel oils to geographically remote areas and/or to relatively high-value niche markets, where the additional costs of identity preservation can be met by the added value of the product.

**CONCLUSION**

The conclusion that engineered oil crops may be best suited to relatively low-volume, high-value markets allows the possible expansion of the target oilseed species beyond the “big four” oil crops to include minor oil crops like safflower or linseed, or even noncrop species like *Cuphea*. Use of such oil crops to produce novel products would have the advantage that segregation from sexually compatible food crop varieties would be fairly straightforward. Another innovative development of transgenic oil crops is the use of the oil as a carrier for recombinant high-value proteins such as pharmaceutical peptides and industrial enzymes. Therefore, the prospects for oil crop biotechnology are now significantly different from the 1990s vision of large-scale “designer oil crops,” but the prospects remain positive, albeit rather more long-term than was originally envisaged. For this new vision to be realized, more investment in research must be coupled with a better appreciation of the economic, managerial, and public acceptability challenges that will confront the new crops.

Genome Rearrangements and Survival of Plant Populations to Changes in Environmental Conditions

Pier Giorgio Cionini
Università di Perugia, Perugia, Italy

INTRODUCTION

The capability of plants to develop plastic response reactions to adapt to changes in environmental conditions is unique in the biological world. However, the idea that the effect of the environment on an organism is, as a rule, physiological—with the genome remaining unchanged—has been a corollary of the biological tenet that a genome must be constant—apart from changes in chromosome number and type—on account of the absolute primacy of DNA over all biological phenomena and of its function as the basis of heredity. The concept that the nuclear genome may be intrinsically plastic due to its content of independent replicative units still meets with incredulity.[1] However, there is a growing consensus of opinion at the present time that changes in genome size and organization may be not restricted to species divergence, and that fluid domains do exist in the nuclear DNA in addition to more stable portions, particularly in plants.

Genomic rearrangements occurring in plant populations have been revealed by changes of genome size, confirmed and specified by molecular investigation, and shown to be related to alterations of plant developmental dynamics and phenotypic characteristics. The following sections show that changes in the nuclear DNA, which as a rule consist of redundancies modulations of repeated DNA sequences and which hence alter the organization of the genome: 1) may differentiate both populations and plants within one and the same population; 2) may have a role in overcoming both changes and changeability of the environment; and 3) may represent either the results of selection processes or direct responses of plant genomes to environmental stimuli.

GENOMIC VARIATION BETWEEN POPULATIONS

Broad bean (Vicia faba) is a good example of genomic rearrangements which may differentiate plant populations. Local populations of this species scattered all along the Mediterranean Basin differ 1.35-fold in genome size. Molecular analyses show that the copy number of both tandemly arranged and interspersed DNA repeats differs between populations and correlates significantly with the genome size.[2] Similar observations have been made in other species. A highly significant, positive correlation was found to exist between the mean genome size of Dasyxylum villosum populations and the altitudes of the stations where they grow.[3] The amounts of DNA and heterochromatin vary according to latitude and altitude in North American lines of maize (Zea mays).[4] The genome sizes of populations of wild barley (Hordeum spontaneum) differ significantly and correlate positively with January temperature at the stations, and BARE-1 retrotransposons have been shown to vary in redundancy in the nuclear DNA of wild barley plants from stations having microclimates sharply differing in solar irradiation and aridity.[5] The amount of nuclear DNA may vary up to 1.32-fold in Italian populations of fescue (Festuca arundinacea) due to variations in the amount of heterochromatin and to changes in the redundancy of DNA sequences which belong largely to a particular fraction of repetitive DNA and are, at least in part, transposable elements or their remnants. The genome sizes of the fescue populations correlate positively with the mean temperature for the year and for the coldest month at the stations and correlate negatively with their latitudes.[6]

The adaptive significance of these genomic changes—their role in buffering environmental pressure and allowing a species to grow in a range of ecogeographical conditions and climates—is clearly shown by their effects on the developmental dynamics of the plants. Cell proliferation and enlargement are affected by the genomic alterations occurring in broad bean populations, and the interactions between these two developmental factors cause the germination power of the seeds and the growth rate of plant organs to differ significantly between populations (compare Ref. 2). In F. arundinacea, the germination power of the seeds and the growth rates of roots and leaves, which are developmental events taking place during winter and early spring, are correlated negatively with the genome size, whereas the height of culms and other quantitative characteristics of plant organs developing later in the warmer season are correlated positively.[7]
GENOMIC VARIATION WITHIN POPULATIONS

Changes in the redundancy of repeated DNA sequences, which result in genome size alterations, may also differentiate plants within populations. An intriguing example of intrapopulation variability of genome size and organization is found in sunflower (Helianthus annuus). In this species, genomic changes are continuously produced during reproduction, even with selfing and homozygosity. Embryos developing in different portions of the flowering head acquire different genome sizes, with a gradient, based on the genome size of the mother plant, that decreases from the pheriphery to the middle of the head. These genomic rearrangements are due to complex, specific changes in the redundancy and methylation of DNA repeats belonging to different sequence families. Another example is D. villosum. Up to a 1.66-fold difference was shown to occur between the genome size of individual plants belonging to given populations of this species, and variability of DNA contents was found to be greater, as a rule, in populations from mountain sites, where the environment is expected to be particularly limiting and/or variable.

It was shown, in both D. villosum and sunflower, that plants differing in genome size also differ in given aspects of their development and, remarkably, in their flowering interval. It is demonstrated in the following section that genomic rearrangements can represent direct responses of the plant genome to environmental stimuli. Therefore, changes of genome size and organization between individual plants of a population may be due to the diversity of environmental (or microenvironmental in the case of sunflower) conditions occurring during the reproduction and/or development of each of them. Intrapopulation variability of genome size and organization may be seen as an evolutionary factor allowing plant populations to withstand the variability of conditions in a given environment.

DIRECT RESPONSES OF THE PLANT GENOME TO ENVIRONMENTAL STIMULI

Genomic rearrangements in plant populations may be the result of selection processes after the occurrence of uncontrolled events in the genome. However, adaptive changes in nuclear DNA also may represent direct responses of the plant genome to environmental variation. The case with flax (Linum usitatissimum) is now classic. When plants carrying given genotypes are germinated and grown under different temperatures and/or in unbalanced mineral nutrients, small and large plants are obtained (genotrophs). These phenotypic characters remain heritable, and genotrophs differ 1.16-fold in genome size. The changes occurring in the nuclear DNA were extensively characterized at the molecular level and shown to be due to copy number variations in given repeated sequence families.

Redundancy modulation of DNA repeats may be specifically controlled. The copy number of certain interspersed repeats increases in plantlets of F. arundinacea obtained by germinating seeds at 30°C, while that of different repeats increases at 10°C. In H. annuus, several repetitive sequence families are more represented in large-size genomes, but there are DNA repeats whose redundancy is greater in the relatively small-size genomes. This specificity suggests that given DNA domains are plastic, not simply instable, with changes occurring under plant-level control and not independently of the genome as a whole.

CONCLUSION

Genomic rearrangements may be the paramount factors, together with the processes of development and reproduction, that allow the adaptive responses of plants to environmental pressure made particularly stringent by immobility. Nucleotypic effects—which can modulate cell proliferation and enlargement and, consequently, developmental dynamics—and/or more specific controls of the nuclear activity may represent the way(s) by which genome rearrangements, determined by quantitative changes of repeated sequences having different origin and chromosomal organization, achieve environmental adaptation. These rearrangements may help to explain the extraordinary plasticity at the morphological and physiological level that is a common feature of plants and may constitute an answer to the debated question about the functional role(s) of repeated sequences in eukaryotic genomes, where they represent the DNA fraction that is by far the largest, especially in plants.

INTRODUCTION

The DNA amount in the unreplicated gametic nucleus is referred to as its C-value. Estimates for nearly 4000 species are accessible in the Plant DNA C-values database. C-values differ more than 1000-fold for plants of similar organismic complexity reflecting differences in ploidy level or amounts of repeated DNA sequences. Genome size is evolutionarily labile and molecular mechanisms responsible for DNA gain or loss are beginning to be understood. C-value and genome size are key diversity characters with important consequences and uses.

DEFINING GENOME SIZE AND DNA C-VALUE

Plants contain DNA in nuclear and organellar (e.g., chloroplast) genomes. This article concerns only the former. Today the term genome may refer to either all the nuclear DNA or only some of it. Thus, a paper on hexaploid *Triticum aestivum* can say that “loci are triplicated in the wheat genome” but also talk of “the three genomes of hexaploid bread wheat.” Genome originally defined a basic (monoploid) chromosome set (x), and the term is restricted to this cytogenetic definition below.

To avoid confusion with chromosome number, Swift introduced the term “C-value” (“C” standing for “Constant”) in 1951. IC refers to the DNA amount in an unreplicated gametic chromosome set (n) of an organism. This usage applies irrespective of ploidy level, so it is important to understand that whereas genome size equals the IC DNA amount in a diploid species, genome size is always less than the IC DNA amount in polyploid species (Table 1). DNA amounts are usually expressed in picograms (pg) or in megabase pairs of nucleotides (Mb) (NB 1 pg = 10^{-12} g; 1 Mb = 10^6 nucleotide base pairs; 1 pg = 980 Mb).

METHODS USED TO ESTIMATE DNA AMOUNTS

Since 1950 DNA amounts have been measured by various techniques. Chemical methods using extracted DNA were little used after the 1960s, while reassociation kinetics was hardly used after the 1970s as faster and simpler techniques were developed that estimate the amount of DNA in single cells or nuclei using microdensitometry, flow cytometry, or video-based image analysis. C-values obtained by these methods are estimates due to inherent technical errors, but complete genome sequencing offers the chance of measuring genome size more exactly.

WHOLE GENOME SEQUENCING

In 2000 the Arabidopsis Genome Initiative published the first “complete genome sequence” in a flowering plant (*Arabidopsis thaliana*). Its genome size was given as 125 Mb, comprising 115.4 Mb in sequenced regions plus a rough estimate of 10 Mb in unsequenced regions.[1] This is an underestimate, as the estimate for unsequenced gaps was too low. 125 Mb disagrees with many estimates made by other methods that placed IC in *Arabidopsis* in the range 147–172 Mb. Moreover, comparison with *Caenorhabditis elegans* (whose 1C-value is known from complete genome sequencing to be 100.25 Mb) gave a 1C DNA amount of approximately 157 Mb for *Arabidopsis*.

In 2002 draft sequences for the first crop species were published. The 1C-value for Indian rice *Oryza sativa* ssp. *indica* was given as 466 Mb[2] with a total scaffold length of 362 Mb plus 104 Mb of masked reads. This value agrees closely with estimates made previously using nonmolecular methods (Table 2).

PLANT DNA C-VALUE REFERENCE SOURCES

DNA C-values for plants come from more than 500 widely scattered original sources. Estimates for angiosperms have been listed for easy reference since 1976[3] and combined in an electronic database since 1997. C-values for angiosperms, gymnosperms, pteridophytes, and bryophytes were pooled in the Plant DNA C-values database,[4] and in 2002, nuclear DNA amounts for almost 4000 plant species (excluding algae) were listed.
INTERSPECIFIC VARIATION
IN DNA AMOUNT

Comparison shows large differences in numbers of estimates and representation between major plant groups (Table 3), and striking variation in C-value within some but not all groups. C-values differ more than 1000-fold in angiosperms (Table 4, Fig. 1), and 450-fold from 0.16 pg in *Selaginella kraussiana* to 72.7 pg in *Psilotum nudum* in pteridophytes. However, C-values vary only 12-fold, from 0.17 pg in *Holomitium arboretum* to 2.05 pg in *Mnium marginatum* in bryophytes, and only 14-fold in gymnosperms from 2.25 pg in *Gnetum ula* to 32.2 pg in *Pinus nelsonii*.

INTRASPECIFIC VARIATION

DNA amount is relatively constant within species and characteristic of taxa, but limited intraspecific variation is known. Such variation can reflect differences in both type and number of chromosomes (e.g., sex and B-chromosomes) and in repeated DNA sequences. A well studied example concerns corn (*Zea mays*), where C-values for different lines can vary by up to 35%. Much of this variation correlates with the presence and size of heterochromatic “knobs” in the genome. Knob number is also related to geographical distribution and may reflect environmental adaptation.[5] However, such examples are few, and recent comparisons of onion (*Allium cepa*) cultivars from widely different regions detected no differences in genome size.

The relative constancy of genome size within species is controversial. Reinvestigation of several claimed examples shows them to be technical artifacts.[6] Variation at the DNA-sequence level may be triggered by events such as wide hybridization. Yet the relative constancy seen in many species suggests that DNA amount may normally be subject to innate controls by counting mechanisms that detect and regulate genome size characters in tightly defined limits. If so, the mechanisms responsible are unknown.

GENOME SIZE EVOLUTION—MECHANISMS OF DNA GAIN AND LOSS

The existence of major differences in C-value raises questions concerning its origin and significance. Huge variation in genome size unrelated to organismal complexity was epitomised as “the C-value paradox” by Thomas in 1971. Such differences are now largely attributed to changes in the proportion of noncoding, repetitive DNA sequences (e.g., transposable elements) and the extent of genome duplication. The puzzle now is to understand the molecular mechanisms and evolutionary pressures that determine the amounts of repetitive DNA in species genomes and thus their genome sizes.[7]

Evolutionary studies were long flawed by the lack of a rigorous phylogenetic framework, but new phylogenetic data recently facilitated meaningful comparisons. Superimposing genome size data onto a robust phylogenetic tree[8] showed that ancestral angiosperms had small genomes (i.e., 1C ≤ 1.4 pg) that are retained in most extant taxa. Possession of large (≥14 pg) and very large (≥35 pg) genomes is a derived condition that arose independently at least six times during angiosperm evolution. A similar analysis for grasses suggested that plants may have a “one way ticket to genome obesity,”[9] as only mechanisms capable of generating rapid genome expansion (such as transposable element amplification) were known. Perhaps plants with small genomes have effective mechanisms to suppress retrotransposition activity, whereas large genomes arose from the release of retrotransposition suppression. More recent studies have

began to shed light on several mechanisms involving recombination that can bring about a decrease in genome size.\[10\] These are poorly understood, but mounting evidence suggests that genome contraction is a widespread phenomenon operating more extensively than once recognised. Plant genome size is evolutionarily labile and the particular genome size of a plant species reflects the dynamic balance between the opposing evolutionary forces of expansion and contraction.\[11\]

**USES OF GENOME SIZE DATA**

DNA C-values have many uses. C-value reference lists provided data for comparative studies at levels ranging from the biosphere to genome organization, and in diverse disciplines including phylogeny, ecology, genomics, cell biology, conservation, physiology, and development.\[12\]

**NUCLEOTYPIC EFFECTS**

DNA affects the phenotype in two ways: first by its genic content, and second by the physical consequences of its

mass and volume, independently of its encoded information (i.e., nucleotypic effects). Nuclear DNA amount shows strikingly close nucleotypic correlations with many widely different phenotypic and phenological characters at cell, tissue, and organismic levels, e.g., chromosome size, chloroplast number, pollen volume, duration of meiosis (Fig. 2), seed weight, and minimum generation time. Thus, C-value is a key factor in scaling the size and rate of development of living systems.

The closer the correlation, the more useful C-value data are as predictors. Interest in C-values as predictors extends to a broad range of ecological and environmental factors, including invasiveness, crop distribution and biomass, and predicting responses of vegetation to global warming or a nuclear winter.[12]

CONCLUSION

Future work on plant DNA amounts offers exciting prospects. New C-value estimates for plant species will soon give complete representation for angiosperm families and for several island floras, and meaningful representation for African, Asian and South-American floras. The availability of genome sequences for several species and of databases linking species C-values with environmental information will allow tests at sequence level of theories about molecular mechanisms responsible for DNA gain and loss, and of possible links between plant ecology, extinction rates, and genome size.

Genome Structure and Gene Content in Plant and Protist Mitochondrial DNAs

Michael W. Gray
Dalhousie University, Halifax, Canada

INTRODUCTION

Complete sequencing of mitochondrial DNA (mtDNA) has provided much information about the size, gene content, and architecture of this organellar genome. One of the striking features of mtDNA is its exceptional physical and organizational plasticity, which stands in marked contrast to its conserved genetic function (i.e., specification of a limited number of components of the mitochondrial electron transport and translation systems). This structural variability is especially pronounced within the plant and protist lineages of eukaryotes; at the same time, these two groups are distinguished in having a generally similar—and larger—gene content than either animal or fungal mtDNAs. Although we are beginning to unravel the pathways of mitochondrial genome restructuring, as yet we have gained only limited understanding of how (and particularly why) the mitochondrial genome has evolved so differently in the various eukaryotic lineages.

MITOCHONDRIAL GENOMES IN PROTISTS

Protists (protozoa and algae) are defined on the basis of exclusion: They are not animals, plants, or fungi. Most protists are single-celled, but multicellular groups do exist (e.g., among the red, brown, and green algae). To date, complete mitochondrial genome sequences have been published for more than 30 different protists (with at least 20 additional sequences in progress), covering a phylogenetically broad range.\(^1\) Protist mtDNAs include the most gene-poor \((\text{Plasmodium falciparum})\) and most gene-rich \((\text{Reclinomonas americana})\) mitochondrial genomes known (Table 1). Most protist mtDNA sequences assemble as single circular molecules, but linear protist mtDNAs are also found (e.g., in the ciliate protozoon, \text{Tetrahymena pyriformis}, and the green alga, \text{Chlamydomonas reinhardtii} (Table 1)).

Protist mitochondrial genomes divide roughly into two basic groups, which have been termed ‘‘ancestral’’ and ‘‘reduced derived’’\(^2\). Ancestral mtDNAs are those that most closely resemble, in gene content and organization, the \(\alpha\)-Proteobacteria-like genome from which contemporary mitochondrial genomes originated.\(^3\) Ancestral mitochondrial genomes are tightly packed, comprising mostly coding sequence. Compared to animal and fungal mtDNAs, they contain extra genes, especially ones specifying ribosomal proteins; they encode strikingly eu-bacterialike large subunit (LSU, 23S-like) and small subunit (SSU, 16S-like) rRNAs, as well as 5S rRNA; they carry a complete or almost complete set of tRNA genes whose tRNA products have conventional, bacterialike secondary structures; with few exceptions, they are mostly intron-poor; they often display eu-bacterialike gene clusters (e.g., \text{rps} and \text{rpl} genes); and they use the standard genetic code for translation.

Ancestral mtDNAs are exemplified in Table 1 by \text{R. americana} and \text{Prototheca wickerhamii}, with the former protist (a jakobid flagellate) having the most eu-bacterialike mitochondrial genome yet described.\(^4\) While not the largest mtDNA in size (those of land plants are considerably larger; see below), \text{R. americana} mtDNA contains a greater number of genes of known function than any other mitochondrial genome, including some 18 protein-coding genes not previously found in any other characterized mtDNA.

Reduced derived mitochondrial genomes (such as those of \text{P. falciparum} and \text{C. reinhardtii}; Table 1) are characterized by extensive loss of genes (tRNA as well as protein-coding); loss of the 5S rRNA gene; aberrant rRNA and tRNA secondary structures; radical divergence in rDNA structure (in both \text{P. falciparum} and \text{C. reinhardtii}, the mitochondrial rRNA genes are fragmented into modules that are rearranged and dispersed throughout the genome); an accelerated rate of sequence divergence (in both protein-coding and rRNA genes); a highly biased codon usage, including complete absence of certain codons; and (often) a nonstandard genetic code. Mitochondrial genome reduction has proceeded to an extreme in \text{P. falciparum}. Not only is its mtDNA the smallest known (a mere 6000 bp), it encodes the fewest genes: only three protein-coding (\text{cob}, \text{cox}1, and \text{cox}3) and two rRNA (\text{rnl} and \text{rns}). In fact, with the exception of \text{cox}3, these genes are...

*LSU, large subunit; SSU, small subunit.

$^a$Roman numerals in parentheses specify intron type (group I and/or group II).

$^b$EC/OP, electron transport/oxidative phosphorylation (nad, NADH dehydrogenase, Complex I; sdh, succinate dehydrogenase, Complex II; cob, apocytochrome b, Complex III; cox, cytochrome c oxidase, Complex IV; atp, ATP synthase, Complex V).

$^c$rps, small subunit; rpl, large subunit.

$^d$Conserved open reading frames (ORFs) of unknown function; unique ORFs; intronic ORFs.

$^e$Head-to-tail tandem repeat of 6 kb unit.

$^f$Length of repeat unit.

$^g$Includes 492-bp subterminal inverted repeats and terminal 40-nucleotide 3' single-strand extensions.

$^i$A single ORF encodes both subunits 1 and 2 (cox1 and cox2) of cytochrome c oxidase.

$^j$Transcripts of most A. castellanii mitochondrial tRNA genes (12 of 15) undergo substitutional editing at one or more of the first three positions of the acceptor stem.

$^k$Genome also encodes the RNA component (rnpB) of a mitochondrial RNase P.

$^l$Circular-mapping genome, but biochemical data indicate a linear genome (see Ref. [6]).

$^m$Genome also contains a nad7 pseudogene.
the only ones that are universally contained in all characterized mtDNAs. In a number of cases, tRNA genes are completely (e.g., P. falciparum) or almost completely (e.g., C. reinhardtii) absent from reduced derived mtDNAs, with nucleus-encoded tRNA species being imported into mitochondria to make up the deficit of tRNAs required for mitochondrial translation.

The division into ancestral and reduced derived groupings serves to emphasize that reduced derived genomes are (in an evolutionary sense) a degenerate form of mtDNA. However, the division into these two categories is not absolute. For example, the A. castellanii mitochondrial genome (Table 1), which has many of the characteristics of an ancestral mtDNA, also displays a few “degenerate” features, such as fusion of the cox1 and cox2 genes into a single ORF; use of TGA to specify an amino acid (tryptophan) rather than translation termination; and loss of many tRNA genes, with transcripts of most of the remaining ones undergoing a novel form of RNA editing. Likewise, the Chondrus crispus (a red algal) mitochondrial genome is mostly ancestral in character but has lost almost all of the ribosomal protein genes that are typically found in ancestral protist mtDNAs (Table 1).

MIITONDOCHRIAL GENOMES IN PLANTS

Land plant mtDNA exemplifies a third type of mitochondrial genome organization, designated expanded ancestral. A hallmark of plant mtDNA is the presence of numerous repeated sequences that are recombinationally active; when such repeats are directly oriented in a circular chromosome, they promote the formation of subcircular products, each of which contains a portion of the master circle. 

A hallmark of plant mtDNA is the presence of numerous repeated sequences that are recombinationally active; when such repeats are directly oriented in a circular chromosome, they promote the formation of subcircular products, each of which contains a portion of the master circle. 

We may expect that further insights into the organization, function, and evolution of plant and protist mtDNAs will come from continued sequencing and comparative analysis of mitochondrial genomes from these two major eukaryotic groups. Particularly interesting is the question of how reduced derived and expanded ancestral forms of mtDNA arose from ancestral forms, and when these transitions occurred in various lineages. A case in point concerns streptophytes (land plants and charophyte algae) and chlorophytes (all other green algae), two monophyletic lineages of green plants that share a common ancestor to the exclusion of other eukaryotes. Although, as noted above, land plants exhibit the expanded ancestral type of mtDNA, primitive chlorophytes (prasinophytes) contain the ancestral mitochondrial genome type typical of many nongreen protists. At what point the evolutionary transition from compact to expanded genome occurred is a question that could readily be explored by judicious sequencing of mtDNA within additional primitive prasinophytes and within the charophyte algae. Comparative mitochondrial genome analysis will not only establish
pathways but may also suggest mechanisms by which mtDNA evolves.[8,9]

Genomic Approaches to Understanding Plant Pathogenic Bacteria

João C. Setubal
Ana C. R. da Silva
Aellex Applied Genomics, Campinas, São Paulo, Brazil

INTRODUCTION

Nowadays, a genomic approach to understanding any bacterium usually requires a detailed description of the organism’s complete genome, which means the entire nucleotide sequence and a list of all potential genes and their known or predicted functions. In the case of pathogenic bacteria, we can then concentrate further study on the genes directly involved in or related to pathogenicity. This approach tries to relate the genome information to what is known about disease symptoms, ideally also including genomic data from host plants. The ultimate goal is to understand the molecular mechanisms of plant-pathogen interactions and their evolutionary history.

BACTERIAL GENOME SEQUENCING

In the whole genome approach, the aim is to determine the DNA sequence of all chromosomes and plasmids present in the organism. The process starts with purification of DNA from a pure culture of bacteria. Using the shotgun technique, bacterial DNA is randomly cut into small (between 1000 and 5000 base pairs (bp) long) pieces that are then ligated into plasmid vectors forming a genomic library of inserts. The sequence of both ends of each insert is determined (each end resulting in a read) by machines called automatic DNA sequencers, each of which is currently capable of delivering about 700 reads per day. Reads must then be assembled into a consensus sequence by computer programs. Because DNA fragmentation is never entirely random, and because of experimental errors as well as the presence of repetitive sequences in the genome, this multiplicative factor is known as the genome coverage. Assembly is not yet an entirely automated process. A few genomic regions will require special care, and some gaps take much longer to close than others. Special software is used to determine the error probability, which can also be expressed as a quality value of each assembled base. The desired result is a gapless sequence with an estimated error of less than one base per 10,000 bp. The process of gap closure and improvement of consensus base qualities is called finishing. Bacterial genomes vary from about one million to 10 million bp. With today’s technology, and using just one sequencing machine, a five-million-bp genome can be completely sequenced, assembled, and finished in about six months by a team of about 10 people.

GENOME ANNOTATION

Once the sequence is available, it should be annotated. This means, at a minimum, finding the potential genes and assigning functions to them when possible. Most, if not all, of this is done in silico, that is, with the aid of computer programs (studied and developed in the field of bioinformatics). Function assignment relies extensively on sequence similarity. This means that we assign a function to a gene in a newly sequenced genome based on its similarity to already available gene sequences in sequence databases such as GenBank (http://www.ncbi.nlm.nih.gov). The most widely used similarity-detection tool is the BLAST program, although many others exist. After being given a new sequence (which can be in nucleotides or already translated into amino acids), BLAST will search a sequence database and possibly return “hits,” that is, database sequences that have similarity to the given sequence above a statistical threshold. If the significant hits found by BLAST come from sequences for which a function has been assigned, then this function can be assigned to the new gene. Genes must then be classified according to their assigned function. Each genome project usually develops its own classification scheme, but most are based on one originally developed for Escherichia coli by M. Riley. For plant pathogenic bacteria, genome annotation requires special attention to genes associated with pathogenicity, and the classification scheme should include categories such as avirulence, hypersensitive response, exopolysaccharides, surface proteins, toxin production and detoxification, and host cell wall degradation. Genes related to flagellar and chemotaxis systems are also important for pathogenicity.

After function assignment, genome annotation can proceed to more specialized analyses. One of these is pathway...
analysis, where an attempt is made to map the genes onto known gene networks. The best-studied of these networks are the metabolic pathways. This mapping can show that one or more pathways are missing or that certain pathways are almost complete, suggesting that the role of missing enzymes is played by genes not recognized as having that function. This can happen because up to 40% of the potential genes in most bacterial genomes do not resemble known genes and thus are not assigned a likely function.

More-sophisticated analyses are required to find genes that are associated with pathogenicity but that are not similar to known genes. One approach makes use of regulatory sequences that are present in the DNA region upstream of genes and that play a part in their transcription and regulation. It is known that in certain cases genes that play similar roles in an organism will have similar regulatory sequences even if the genes themselves are not similar to each other (but similarity of regulatory sequence does not always imply similar function). If the regulatory sequence, R, of certain pathogenicity genes is known, then one can search for additional co-regulated genes by searching for a sequence similar to R. The similarity may be subtle and may therefore require the use of sophisticated techniques such as hidden Markov models. On the other hand, the conservation of R may happen even across species, such that an R sequence identified in one organism can be used to help identify genes in the same family in another species.[5]

Another approach to gain a deeper understanding of pathogenicity genes comes from careful and detailed comparison of the genomes of two or more related species. If both species are pathogenic, one may try to understand the similarities or differences they have in terms of symptoms or host range, or both, through the study of their shared or dissimilar genes. Such studies show the importance of having the complete genome of each organism so that conclusions about the absence of genes can be drawn more reliably. Complete genomes also make it possible to build gene/protein sequence databases. When including several organisms, such databases allow multiorganism comparisons that can yield important insights. For example, van Sluys et al.[9] used this approach to obtain a list of genes shared by eight plant-associated bacteria; such genes are good candidates to be fundamental in plant-bacteria interactions. The inclusion of genomic information from plants (such as Arabidopsis thaliana and rice, whose genomes have been sequenced) in these databases will turn them into even more powerful resources.

The topic of horizontally transferred genes is also of particular relevance for pathogenicity studies.[7] Genes are horizontally (or laterally) transferred when they enter the organism not through inheritance but through invasion by phages or mobile genetic elements. If such genes do not kill the organism but are instead kept in its genome, this means that they confer some selective advantage. Lateral transfer between bacteria is well documented in the literature. One example is from Da Silva et al.,[12] who present strong evidence that many pathogenicity genes found in Xanthomonas axonopodis pv. citri have been laterally transferred. Conversely, sometimes genes are lost because they no longer are important for the organism’s survival, and their presence in a related species may suggest their continued importance in the environment of the other organism.

FUNCTIONAL STUDIES

Genome annotation forms the foundation for follow-up functional analyses in the laboratory, which will confirm or refute the hypothesis raised in silico. One technique is targeted gene disruption or knock out. This is commonly done using a special plasmid vector that does not replicate inside the bacteria under study and which has been engineered to carry part of the gene to be knocked out. After insertion of the vector, which also carries an antibiotic resistance gene, into the bacteria, it will either insert into the genome by homologous, site-specific recombination or be lost. Selection of bacteria for those expressing the vector-encoded antibiotic resistance yields cells with the vector inserted into the target gene.

Another laboratory technique is the gene expression microarray. A DNA microarray (a gene chip) is made by depositing short DNA sequences of many or all genes from a genome on a glass slide in high densities (more than 2000 spots in 2 cm²). Similar to the traditional Northern blot technique, microarrays are probed with labeled mRNA from cells so that it hybridizes to immobilized, homologous target DNAs. If the RNA was labeled with a fluorescent tag, then the intensity of fluorescence in each spot is proportional to the amount of RNA retained by the target DNA. When RNA has been isolated from bacteria exposed to two different environmental or cultural conditions, the preparations can be labeled with different fluorescent tags. Hybridization of these probes to identical microarrays, followed by suitable image and data processing, reveals genes that are differentially expressed under those conditions.

CONCLUSION

As of this writing, five plant-pathogen bacterial genomes have been completed and published:

- Xylella fastidiosa, strain 9a5c[10]
- Agrobacterium tumefaciens C58[6,11]
- Ralstonia solanacearum[8]
Xanthomonas axonopodis pv. citri\cite{12}
Xanthomonas campestris pv. campestris\cite{12}

These projects have yielded a wealth of genomic information and have placed phytopathology at a new level. For a detailed review of these projects, see Van Sluys et al.\cite{9} No concrete and effective new ways to deal with the diseases caused by the plant pathogens have yet resulted from these projects. However, most researchers have no doubt that these genomic approaches will eventually yield disease management benefits. This may still take a great deal of time and effort; genomics is only the first step.

Genomic Imprinting in Plants

Daphné Autran
Jean-Philippe Vielle-Calzada
CINVESTAV—Unidad Irapuato, Irapuato, Mexico

INTRODUCTION

The differentiation and fusion of male and female gametes to initiate the formation of a new organism is a common feature in the life cycle of higher eukaryotes. In the ovule of flowering plants, the embryo develops following fertilization of the haploid egg cell by one of the sperm cells delivered by the pollen tube, giving rise to a diploid zygote. A second sperm cell fuses with the binucleated (homodiploid) central cell to give rise to the triploid endosperm having a 2:1 maternal to paternal genomic ratio. The embryo and the endosperm, each with different ploidy and parental gene dosage, coordinately develop inside diploid maternal tissues.

Plant gametes carry distinct haploid genetic constitutions that are usually considered to be functionally equivalent, both contributing active alleles that will influence the phenotype of the newly formed individual. For some traits, the activity of an allele is influenced by the parent from which it came. Parent-of-origin effects can be the consequence of differences in transcription between paternally and maternally inherited genes in the embryo and/or the endosperm. Genomic imprinting refers to a specific type of genetic regulation resulting from a mitotically stable epigenetic modification that consistently inactivates one of the parental alleles. Loci that are regulated by genomic imprinting will be differentially expressed in a parent-of-origin dependent manner. If a gene is controlled by genomic imprinting, transcription occurs exclusively from one of the two parental gene copies. Hence, imprinted genes are inherited in a silent state from one of the two parents, and in a fully active form from the other. Genomic imprinting results in a functional nonequivalence of parental genomes during embryogenesis and/or endosperm development. Due to particular features of the plant life cycle, it is often difficult to distinguish between the effects of maternal factors and the consequences of genomic imprinting on the regulation of a specific locus. A maternal effect refers strictly to a genetic definition: Any reciprocal cross resulting in differential phenotypes that are exclusively determined by the genotype of the female parent (or the megagametophyte) is the consequence of a maternal effect. This broad type of parent-of-origin effect can result from the action of imprinted genes, but also from: 1) gene products that are stored in the cytoplasm of the egg cell; 2) dosage-sensitive genes acting in the embryo and/or the endosperm; or 3) products encoded by the genome of maternally inherited organelles. Maternal effects caused by cytoplasmic protein storage and genomic imprinting are clearly distinguishable if transcripts are present only prior to fertilization but not after (perdurance, implying a maternal effect sensu stricto) or if transcripts are present only after fertilization but not before (imprinting).

SEED DEVELOPMENT AND GENOMIC IMPRINTING

Whereas genomic imprinting has been extensively studied in mammals and insects, the first demonstration of a gene regulated by genomic imprinting was obtained for the r1 locus in maize.\(^1\) Subsequently, pioneering studies by Lin\(^2\) and Kermicle used exceptional mutants in maize to manipulate genome dosage in the endosperm. In the indeterminate gametophyte (ig) mutant, several haploid nuclei fuse in the central cell, generating an endosperm of variable ploidy. By conducting reciprocal crosses involving genotypes with different ploidy levels, they showed that deviations from the normal 2:1 maternal to paternal genome ratio in the fertilized central cell resulted in an aborted endosperm. They inferred that the parental origin of each of the genomic contributions is crucial for normal endosperm formation. Similar conclusions were obtained from lines carrying chromosomal translocations in maize: Deletions of particular regions of a specific chromosome that were paternally inherited lead to a significant reduction in endosperm growth. The defects are not rescued by providing an additional maternal copy of the translocated region.\(^3\) These important results allowed dosage-dependent effects to be distinguished from the occurrence of genomic imprinting during endosperm development.
The FIS Class of Genes Is Regulated by Genomic Imprinting in *Arabidopsis*

More recently, direct evidence of genomic imprinting has been obtained for a handful of genes.\[4\] Whereas in maize several genes are differentially expressed in a parent-of-origin–dependent manner, only members of the FERTILIZATION-INDEPENDENT SEED class of genes (FIS) have been shown to be regulated by genomic imprinting in *Arabidopsis*. These three *Arabidopsis* genes were identified on the basis of their gametophytic maternal effect mutant phenotype, which causes seed abortion, and by their ability to initiate endosperm formation in the absence of fertilization.\[5\] Female gametophytes of *medea* (*mea*), fertilization independent endosperm (*fie*), and *fis2* give rise to abnormal seeds irrespective of the paternal genomic contribution. The embryo and/or endosperm of *fis* mutants show an increase in cell number, suggesting that the primary role of the FIS genes is to restrict cell proliferation. Consistent with this role, *MEA* and *FIE* encode Polycomb group proteins (PcG). In *Drosophila*, these proteins are known to form repressor complexes that regulate higher-order chromatin structure during animal development. The phenotypes shown by *mea* and *fie* suggest that their function is conserved in flowering plants. The *Arabidopsis* FIS2 gene encodes a Zn-finger protein implicated in the formation of the PcG complex.\[6\] All FIS genes are expressed during female gametophyte development prior to fertilization; *MEA* and *FIE* are coexpressed in the embryo and the chalazal domain of the free nuclear endosperm, whereas expression of FIS2 could only be detected during the early stages of endosperm development. A combination of in situ hybridization and reverse-transcriptase polymerase chain reaction (RT-PCR) experiments provided the evidence that following fertilization *MEA* is only transcribed from maternally inherited copies in both the developing embryo and the endosperm, demonstrating that the gene is regulated by genomic imprinting.\[7\] Similar approaches were used to show that *fie* and *fis2* are also imprinted.\[8\]

**Genomewide Mechanism of Paternal Imprinting in *Arabidopsis***

Because plant embryos can develop from somatic cells or microspores, it was generally considered that the maternal contribution is not crucial for embryogenesis. Recent studies in *Arabidopsis* suggest that early embryo development is mainly under maternal control due to a combination of maternal products deposited in the female gametophyte and a genomewide mechanism of paternal imprinting.\[9\] Using reciprocal crosses to wild-type, more than 20 genes detected by gene trap approaches were shown to be expressed only when maternally inherited (Fig. 1). Analysis of gene expression using allele-specific RT-PCR demonstrated that the absence of transcription resulted from the silent state of the endogenous genes and not from the inactivation of the reporter gene present in the gene trap transgenic construct. All of these genes are randomly distributed across the *Arabidopsis* genome and encode a wide range of proteins, showing that the observed paternal silencing is not limited to a specific genomic region or a particular developmental mechanism. For some of these genes the activation of the paternal genome occurred 96 hours following fertilization, i.e., at the midglobular stage of embryo development. The correlation between allele-specific silencing and genetic activity was demonstrated by analyzing early embryonic defects in *emb30*, a recessive embryo-lethal mutant defective in the first zygotic division of *Arabidopsis*. Heterozygous *emb30*/*EMB30* embryos that inherited a wild-type allele from the male parent did show a mutant phenotype, confirming that early defects cannot be rescued by an active paternal *EMB30* allele. The degree of inactivation and the timing of initiation of paternal transcription may vary from gene to gene.\[10\] Additional experiments have suggested that some specific genes or their regulatory elements escape this genomewide mechanism of parental silencing and are active early following fertilization. Baroux et al.\[11\] showed that embryo abortion can be induced as early as the 2- to 4-cell stage using a transactivation system that depends on the transmission of the elicitor through male gametes. These results suggest that either some regulatory elements can escape parental silencing or that the timing and extent of activation are altered by the specific regulatory system used.

---

**Fig. 1** Silencing of paternally inherited gene activity during seed development in *Arabidopsis*. (A) When an enhancer detector is used as a female parent in crosses to wild-type, reporter gene expression is detected in the developing embryo and endosperm of F1 seeds 50 hours after pollination (HAP). (B) When the same enhancer detector is used as the male parent in crosses to wild-type, reporter gene expression is absent from the embryo and the endosperm 50 HAP. (Figure courtesy of Gerardo Acosta-García.) *(View this art in color at www.dekker.com.)*
imprinting (in this case, the cyclin B1 promoter and the heterologous pOp promoter), or that the activity of the paternal genome is not completely abolished but rather attenuated by a very low level of transcription during early seed development.

THE REGULATION OF GENOMIC IMPRINTING

Based on the existing evidence, it currently appears that two distinct classes of imprinting mechanisms regulate seed development in flowering plants. A delayed activation of the paternal genome indicates that a wide mechanism of imprinting ensures that both parental genomes are not functionally equivalent following fertilization. In addition, specific loci such as members of the FIS class of genes could be imprinted until later stages of seed development, as has been shown for MEA. In both cases the evidence implies that a mechanism of allele-specific inactivation must be established during gametogenesis. Maintenance of the resulting imprint must be ensured through successive haploid mitotic cycles and finally lost in diploid cells at some stage of sporophytic development before being reestablished in the germline.

Despite extensive research in mammals, the regulation of genomic imprinting is far from understood. To date, the most common mechanism associated with the regulation of genomic imprinting in plants is DNA methylation. In animals, there is a correlation between methylation (epigenetic modification of CpG to 5-methyl-CpG) and the imprinted status of most of the genes described. In Arabidopsis, reciprocal crosses of transgenic methyltransferase 1 antisense (met1a/s) to wild-type diploids produced seeds with defects similar to those observed in interploidy crosses. For example, hypomethylated females crossed to wild-type males gave rise to paternalized seeds containing a large endosperm and embryo. The reciprocal cross leads to the opposite effect. Moreover, mutations in the FIS genes can be rescued by reducing global methylation levels by either met1a/s or ddm1 pollen. DDM1 is a member of the SWI/SNF family of ATP-dependent chromatin remodeling enzymes, and ddm1 mutations reduce genomic methylation by 70%.

In most cases, rescue of the embryo or the endosperm occurs even if the paternal genome carries a fis mutant allele, suggesting that unknown genes can substitute for FIS function in early seed development, and that FIS paternal alleles remain silent even in a hypomethylated context, implying that their regulation most likely involves additional mechanisms yet to be discovered. Additional epigenetic mechanisms involving chromatin remodeling, histone modification, or specific methylation could ensure the imprinted memory necessary for the occurrence of mitotically stable reversible changes in gene expression. The fact that FIS genes encode chromatin remodeling factors and are regulated by genomic imprinting suggest that their target genes, involved in the regulation of seed development, are probably also imprinted. Interestingly, DEMETER (DME)—a DNA glycosylase with nuclear localization domains—has been shown to be required for the expression of the MEA maternal transcript in the developing endosperm. DME is preferentially expressed in the developing endosperm, and homozygous dme plants show a maternal effect, suggesting that DEMETER could also be imprinted.

CONCLUSION

How did genomic imprinting evolve? Haig and Westoby proposed that parent-of-origin specific effects evolved as a consequence of an intragenomic conflict over the allocation of nutrients from the mother to its offspring. This theory predicts that paternal interests favor selfish fitness for their own offspring, and not the fitness of full siblings from a distinct father. Therefore, paternally expressed genes would tend to promote the growth of the embryo. In contrast, maternal interests favor survival of all siblings irrespective of their paternal origin. Maternally expressed genes would tend to optimize overall survival by reducing the size of the embryo. The role of genomic imprinting in regulating parental interests may have been conserved in organisms that have acquired placental habits. Supporting evidence has been provided by studies of imprinted genes in mice and humans, but also in plants. Most imprinted genes identified in mammals fit the parental conflict theory. In flowering plants, the manipulation of gene dosage in the endosperm and the embryo of maize and Arabidopsis has shown that increasing paternal dosage promotes growth of the endosperm, whereas an increase in the maternal dosage reduces its size. In Arabidopsis, disruption of MEA leads to overproliferation of embryonic cells, albeit embryos arrested at an earlier stage than wild-type. In contrast to mammals, genes exclusively transcribed from the paternally inherited copy have yet to be discovered in flowering plants.

Although parental conflicts at the gene level are just starting to be investigated in flowering plants, the elucidation of the genetic basis and molecular mechanisms regulating a genomewide paternal silencing during early seed development has yet to be initiated. The synchronous evolution of parent-of-origin effects in mammals and flowering plants could be closely related to their sexual habits. In that regard, the investigation of imprinting in apomictic plants, in combination with the fast emergence of genomic technology, should provide important clues to determine the number of genes that are regulated by
genomic imprinting and their overall impact on plant growth and development.

Genomics of Fungal Plant Pathogens

Brett M. Tyler
Virginia Bioinformatics Institute and Department of Plant Pathology, Physiology and Weed Science, Virginia Polytechnic Institute and State University, Blacksburg, Virginia, U.S.A.

INTRODUCTION

Organisms historically called plant pathogenic fungi include two distinct lineages of organisms, those in the kingdom Mycota (true fungi) and those in the kingdom Stramenopila (oomycetes).[1] Both groups of plant pathogens are heterotrophic, grow as multinuclear filaments and/or as single cells, and have evolved the ability to neutralize the defense responses of their plant hosts.[1] The advent of genomics has transformed the molecular biology of fungal plant pathogens from a focus on individual genes and their contributions to infection to the contributions of large gene networks. Highlights of what genomic studies have revealed include the presence of large, rapidly evolving multi-gene families encoding proteins and metabolic pathways that potentially contribute to infection, the presence of extensive redundancy of function among these genes, and the extensive remodeling of pathogen metabolism during infection.

PLANT DEFENSE AND PATHOGEN ATTACK

Plants are largely resistant to infection by microbes as a result of well-developed defenses.[2] Constitutive defenses include physical and chemical barriers. Defense responses induced by infection include production of reactive oxygen species, small-molecular-weight antimicrobial phytoalexins, hydrolytic enzymes and other antimicrobial proteins called Pathogenesis-Related (PR) proteins, and a form of programmed cell death called the hypersensitive response. Plant pathogens, including fungi and oomycetes, have evolved mechanisms to succeed in the face of host defenses. They must penetrate or circumvent physical barriers. They must either avoid or suppress the triggering of inducible defense responses. They must protect themselves against constitutive defense mechanisms and against defense responses they cannot avoid inducing. Finally, once established inside the plant host, the pathogens must adapt to the nutritional environment of the tissue sufficiently well to reproduce. These mechanisms determine the pathogenicity and virulence of the pathogen; in plant pathology, “pathogenicity” refers to the fundamental ability to infect the plant while “virulence” refers to the amounts of disease caused, although in practice there is considerable overlap in the two concepts. A detailed understanding of the mechanisms of pathogenicity and virulence in plant pathogens will provide the basis for new and effective means for controlling plant disease.

Genetics and molecular biology have been used to identify many individual genes that contribute to pathogenicity and virulence. Examples include genes encoding enzymes that degrade plant defense compounds such as reactive oxygen species, phytoalexins or phytoanticipins, genes for inhibitors of plant hydrolytic enzymes, and genes for transporters that remove toxic plant metabolites. Further examples include genes specifying toxins, genes encoding enzymes that degrade plant physical barriers, and genes required for elaboration of morphological structures required for invasion of plant tissue such as appressoria and dikaryons.[3] These studies have also characterized genes known historically but inaccurately as “avirulence genes.”[4] These genes encode proteins that either directly or indirectly interact with plant defense receptors encoded by major resistance genes. Deletion or loss of expression of avirulence genes can enable fungal and oomycete pathogens to expand their host range to plants containing major resistance genes. The benefit to the pathogen of avirulence genes is best understood in bacterial pathogens, where these genes have been shown to encode effector proteins that can enter the plant cell to increase the susceptibility of plant tissue to infection;[4] it is presumed that the function of many fungal and oomycete avirulence genes is similar, because some products of those genes appear to interact with plant defense receptors that have an intracellular location.[1] Some fungal avirulence genes encode extracellular proteins that are toxins or can inhibit plant hydrolytic enzymes.[1] The advent of genomics and bioinformatics techniques for rapidly characterizing very large numbers of genes has made it possible to examine the roles of all these genes, or genes like them, in an integrated fashion within the genome of a single pathogen.[3,5] The interaction between a pathogen and its plant host clearly involves the interplay of a very large number of genes, many of which may have redundant, overlapping, and/or interconnected functions. Genomics and bioinformatics now make it
possible to investigate the interaction of fungal and oomycete pathogens with plants at a whole genome to whole genome level. The contributions of genes that have individually identifiable functions and those that do not now can be jointly characterized.

DNA SEQUENCING OF FUNGAL AND OOMYCETE GENOMES

High throughput DNA sequencing of mRNA or chromosomal DNA provides a way of rapidly creating an inventory of large number of pathogen genes and predicting their functions.

Expressed Sequence Tags

Expressed Sequence Tags (ESTs) are created by DNA sequencing of cDNA clones copied from mRNA from tissues of interest such as hyphae or spores. Generally, each randomly chosen clone is sequenced just once, from the end corresponding to the 5' end of the mRNA. ESTs thus provide information about genes transcribed into mRNA in specific tissues. The frequency with which ESTs are obtained from a given gene can also provide a semiquantitative measure of the levels of expression of that gene in the tissue. EST collections can also be obtained from an infection site containing a mixture of plant and pathogen tissue; in this case the plant or pathogen origins of the EST sequences can be identified bioinformatically. The limitations of ESTs are that an EST usually contains only a fragment of the corresponding gene sequence, and many gene sequences are absent from EST collections because the mRNA levels of those genes are very low in the tissues from which the cDNA libraries were made.

Despite their limitations, the cost effectiveness of EST sequencing has led to EST collections being developed for a wide range of fungal and oomycete plant pathogens.\cite{5,6} As of July 2005, National Center for Biological Information (NCBI’s) dbEST database contained more than 100 ESTs for each of 27 species of fungal plant pathogens and 5 species of oomycete plant pathogens. Many of these ESTs are also available at the COGEME Phytopathogenic Fungi and Oomycete EST Database (http://cogeme.ex.ac.uk/).\cite{6}

Genome Sequencing

A more costly, but much more complete approach to cataloging the genes present in a species is to sequence the entire genome. The genome sizes of fungal plant pathogens range from 9 to 70 Mb, while those of oomycete plant pathogens range from 25 to 240 Mb. The cost of DNA sequencing has rapidly dropped as automation and new technologies have been developed, making it increasingly feasible to determine the genome sequences of these relatively small genome sizes (compared to human 3000 Mb). Draft genome sequences, produced by randomly sequencing fragments of genomic DNA of defined sizes, are particularly inexpensive. Table 1 lists fungal and oomycete plant pathogens for which a draft or finished genome sequence is either available, or currently being completed.

Comparative Sequencing

Comparisons of the genome sequences of closely related species can provide valuable information about which genes are highly conserved and which are rapidly evolving, for example, in response to selection pressure from the plant host. Comparisons of the sequences of \textit{P. sojae} and \textit{P. ramorum} have been especially useful in this respect.\cite{7} Comparisons of the genome sequences of \textit{A. gossypii}\cite{8} and \textit{M. grisea}\cite{9} with their non-pathogenic relatives \textit{Saccharomyces cerevisiae} and \textit{Neurospora crassa}, respectively, have also been useful. As the cost of sequencing continues to fall, and with the advent of dramatically faster and cheaper technologies such as pyrosequencing, extensive comparative sequencing will likely become more and more feasible.

FUNCTIONAL GENOMICS OF FUNGAL AND OOMYCETE PLANT PATHOGENS

Functional genomics refers to high throughput experimental methods to determine the functions of genes identified from ESTs and genome sequences. Broadly, these methods fall into two categories: high throughput measurements of the levels of cellular components such as mRNA (transcriptomics), and high throughput generation of mutations that destroy or inhibit the functions of genes identified in genome sequence.

Transcriptomics

Microarray analysis is the most widely used method for high throughput measurement of mRNA levels in fungal and oomycete plant pathogens.\cite{10} Microarrays consist of hundreds or thousands of DNA probes attached to a solid support. Fluorescently labeled cDNA or cRNA derived from the mRNA of interest
is then hybridized to the microarray, and the intensity of hybridization is measured for each probe. Transcriptional profiles provide valuable information about when and in what tissues genes are expressed, e.g., in spores or during early or late infection. Thus they can provide information about possible functions even when there is extensive redundancy of function. The most common forms of arrays are cDNA arrays in which amplified cDNA fragments are attached to glass slides, “long-oligo” arrays in which synthetic oligonucleotides 50–70 nucleotides in length are attached to glass slides, or AffymetrixTM GeneChipsTM in which oligonucleotides of 25 nt in length are synthesized in situ on silicon chips. cDNA arrays have been created for *A. flavus*, *Blumeria graminis*, *Cryphonectria parasitica*, *F. graminearum*, *F. verticillioides*, *M. gramineola*, *S. sclerotiorum*, *Verticillium dahliae*, and *P. sojae*, long-oligo arrays have been created for *M. grisea*, and GeneChips have been created for *P. sojae*, *P. infestans*, *F. graminearum*, and *U. maydis*.

### Mutational Analysis (Reverse Genetics)

Transformation of plant pathogenic fungi with exogenous DNA can be used to generate large collections of mutants in genes of known sequence. In species where incoming exogenous DNA integrates by homologous recombination at high frequency, deletions or gene replacements can be targeted to specific genes; this approach has been used in a high throughput manner in *A. gossypii*, *Cochliobolus heterostrophus*, and *U. maydis*. In species where integration by heterologous recombination occurs, genes in the chromosomes can be disrupted by insertion of the incoming DNA, and the site can be later characterized by sequencing the boundaries of the insertion. *Agrobacterium*-mediated transformation and restriction-enzyme mediated insertion have been particularly effective for this, and both have been used extensively in *M. grisea*. Alternatives to gene disruption strategies include gene silencing and TILLing. Gene silencing

has been used to test the functions of individual genes in fungi and oomycetes,[11] and TILLing has been used extensively in plants,[14] but neither approach has yet been implemented at a high throughput level in plant pathogenic fungi or oomycetes.

**Forced Expression**

Because many genes in a complex interaction such as that between a plant and pathogen may have overlapping or redundant functions, disruption or silencing of an individual gene may not be informative as to its role. An alternative approach is to force the expression and/or overexpress a gene so that its contribution becomes exaggerated to the point that it can be characterized. The roles of some individual genes have been characterized by making transgenic pathogen strains overexpressing a gene. However, technologies for doing this on a high throughput scale are still under development. An alternative approach is to overexpress pathogen genes in the host plant and then measure changes in resistance or susceptibility. This approach has been used very effectively on a high throughput scale in *P. infestans*, using a plant virus vector.[15]

**INFERENCES FROM GENOMICS STUDIES**

Although relatively few fungal or oomycete genome sequences have yet been analyzed, several themes have emerged from those that have been analyzed. The most prominent theme is the extensive diversification of gene families associated with pathogenicity and virulence in these genomes. For example, in *M. grisea*, extended gene families were identified with similarity to the known *M. grisea* pathogenicity gene PTH11, which encodes a novel seven transmembrane-spanning-domain protein, to biosynthetic genes for polyketide and non-ribosomal peptide toxins, and to the *Cladosporium fulvum* Avr4 gene, which encodes a chitin-binding protein.[9] In *P. sojae* and *P. ramorum*, extended gene families were identified with similarity to genes encoding protein toxins and protease inhibitors, to *P. sojae* avirulence gene Avr1b-1, and to genes encoding ABC transporters.[7]

**CONCLUSIONS**

Genomic approaches are changing our understanding of plant–pathogen interactions, enabling them to be studied as an interaction between large networks of genes in each organism. Increased sequencing of genomes, cheaper and more powerful functional genomics technologies including proteomics and metabolomics, and increased sophistication in methods for bioinformatic analysis and mathematical modeling of genetic interactions will dramatically accelerate this revolution over the next 10 years.

INTRODUCTION

Plant genetic resources—varying from wild relatives of crops to farmers’ varieties—form the raw materials of crop improvement programs. They have proven economic value to improve a wide range of traits, ranging from disease and pest resistances to improved yields and improved agronomic traits, and are critical to global food security. Their importance has long been recognized, and many national and international institutes have been set up to acquire, increase, store, distribute, and use them for crop improvement. This article briefly reviews the steps involved in the acquisition of germplasm, from the planning and conduct through the follow-up stages of germplasm collecting expeditions.

WHY COLLECT GERMPLASM?

Genetic resources, including landraces (farmer varieties) and wild relatives of our crops, are crucial to global food security. These resources are distributed worldwide, but with a concentration of diversity south of the tropic of Cancer (Fig. 1). The size and distribution of economic gains from yield increases in the major U.S. crops attributable to genetic improvements is impressive. Farmers have benefited from a 1% yield increase per year, half of this due to genetic improvements. Based on these assumptions, a one-time permanent estimation of the worldwide value to consumers of germplasm, as assessed by reduced food prices, is between $8.1 billion and $15.4 billion. Although the United States enjoys 50–60% of these benefits, consumers in developing and transitional economies enjoy between $6.1 and $11.6 billion of the benefits. Whereas the ultimate goal of germplasm acquisition is crop improvement, a major subsidiary benefit is the availability of these collections for characterization studies (e.g., taxonomic studies) to aid breeders.

Germplasm may be acquired either by exploration or from existing germplasm collections. For the major crops, relatively good coverage exists in some national programs and in the International Agricultural Research Centers (IARCs) of the Consultative Group on International Research (CGIAR). Examples are the International Rice Research Institute (IRRI) in the Philippines and the International Maize and Wheat Improvement Center (CIMMYT) in Mexico. However, collecting needs remain, even in the major crops; and many minor orphan crops have major collecting needs.

HISTORY OF PLANT COLLECTING

Germplasm acquisition has a long history, with records of exchanges between cultures dating back thousands of years. International germplasm collecting expeditions in the 16th and 17th centuries were largely focused on exotic foods and ornamentals for botanic and university gardens. The Royal Botanic Gardens at Kew, England, established a widespread network of botanic gardens, resulting in the movement of enormous numbers of samples worldwide. Botanic gardens published new collections in seed lists that facilitated free worldwide exchanges of germplasm. The number of introductions brought into cultivation by botanic gardens exceeded 80,000.

Private industry and gardening societies also collected, maintained, and exchanged germplasm, as did state and federal agencies. The early 19th century saw the development of major national collections, such as the All-Union Institute of Plant Introduction in St. Petersburg, Russia, later renamed the N.I. Vavilov All-Union Scientific Research Institute of Plant Industry (VIR). This institute, initiated by Nicolay Vavilov, sponsored collections worldwide and established an extensive system of national institutes to maintain, characterize, and use them. The U.S. Department of Agriculture (USDA) plant exploration program began formally in 1898 with the creation of the Section of Seed and Plant Introduction that evolved into an organized U.S. National Plant Germplasm System (NPGS). From 1898 to 2001, the USDA conducted 540 explorations, 80% to foreign countries.
Explorations were made in every year except the war years, 1942–1945. Today the NPGS is the largest national germplasm system in the world, with 450,000 samples covering more than 10,000 species. At least a quarter of the yearly distributions made by the NPGS are to scientists outside the U.S. National genetic resources programs are established in many other countries, and over six million collections are estimated to occur in ex situ genebanks worldwide. In the future, the International Treaty on Plant Genetic Resources for Food and Agriculture (IT) will govern access to germplasm for Plant Genetic Resources for Food and Agriculture, which has been agreed to by country members of FAO and will enter into force upon ratification by the required number of countries. The implementation of the Treaty will determine the future ease of access.

ACCESS

In the initial stage of germplasm collecting, and continuing through the 1960s and 1970s, most germplasm was generally freely available. Exchange of plant genetic resources is now the subject of the IT, which was adopted by the FAO Commission on Plant Genetic Resources in November, 2001, and will become international law once it is ratified by 40 countries. The treaty establishes a multilateral system for the exchange of key crops and forage species. National laws of countries that are parties to the IT must be adjusted to conform. In some countries, national genetic resources programs are not yet established or their regulations have not yet been implemented. In others, access (including that required for plant exploration) has already been subject to new regulations. In order to address developing countries’ concerns regarding benefit sharing, which is required by the new treaty, some developed nations are exploring the association of increased nonmonetary benefits, such as student training; the transfer of equipment, information; and technology; and other collaborative exchanges, with agreements on access.

PLANNING AN EXPEDITION

Extensive background work is critical to the success of germplasm explorations, beginning with the definition of...
goals. Most explorations are initially intended to fill in gaps in current collections, as determined by taxonomic, ecological, or geographic criteria. Thus, an exhaustive search of available collections (national genebanks, international genebanks, and individual research collections) should be made before an exploration is contemplated. Some apparently available germplasm is not accessible because it is not increased, is diseased, or is otherwise restricted. Sometimes, discordant taxonomies of the same group make the task of comparing all sources of information difficult because of competing names and classifications (see an example in wheat at http://wheat.pw.usda.gov/ggpages/DEM/9IWGS/taxonomy.html and potato).\[3\] Searching for germplasm currently available in genebanks is simplified by the on-line availability of the germplasm in the genebanks of the CGIAR http://www.singer.cgiar.org/) and the U.S. NPGS http://www.ars-grin.gov/npgs/), but germplasm holdings of many smaller genebanks require direct correspondence with managers. The determination of all germplasm collections available is facilitated by indices of common collections held in common among genebanks,\[7\] although such indices are rare. Monographs (treatment of a particular group) and floras (treatment of all plants in a particular region) provide locality data, as well as identify regional herbaria. (An index of herbaria, Index Herbariorum, is available at http://www.nybg.org/bsci/ih/ih.html.)

Once the goals of an exploration have been identified, successful planning involves attention to access agreements, identifying and establishing contacts with knowledgeable in-country field collaborators, timing, logistics, and field equipment.\[4,8,9\] The new political climate can make access agreements difficult to obtain, and planning must begin well in advance. Agreements with host countries should clearly state details of the collection, export, increase, intended use, and distribution of germplasm. An experienced collaborator—ideally one who knows the logistics, culture, and crop—is essential. Timing of the expedition is crucial, especially for highly seasonable species for which differences in rainfall the prior or current year can drastically affect the growth of plants in a given year and the availability of germplasm. Germplasm collecting expeditions are expensive and time-consuming. Logistical challenges of some areas are often daunting, and investments in reliable equipment, especially vehicles, pay off. Field equipment needs vary according to the crop and terrain, but a geographic positioning system (GPS—determines latitude and longitude), altimeter (in mountainous areas), and maps are essential for reliable locality data. Some maps can be obtained only in country. Time must be allotted at the beginning of the exploration to purchase maps, visit herbaria, and meet local officials.

CONDUCTING THE EXPEDITION

Important considerations in the field include number of sites to visit, number of plants to sample, sampling techniques, and the number and type of propagules to sample from each plant.\[4\] These differ among species with different breeding systems and dispersal mechanisms. The number of collecting sites must be planned to maximize the amount of genetic variation sampled, within the constraints of time and funding. Marshall and Brown and others\[4\] proposed mathematical formulas for these that are useful when germplasm is common, as when collecting landraces. For many crops, populations are often so scarce that these theoretical calculations give way to the practicality of collecting sufficient germplasm of all populations encountered to ensure a successful germplasm increase, taking care to maintain populations intact in the wild. Collecting methodologies depend on a number of factors, including the biology of the targeted taxon and the objectives of the expedition. Different types of propagules, whether seed or vegetative, require different sampling and handling techniques in the field.

Local markets provide a relatively easy means of collecting landraces for many crops, and are important sources of information on the diversity of a crop in a given area. However, visits to local farmers provide better information on plant characteristics, uses, and cultural methods; higher quality germplasm; and varieties grown only for home consumption. Visiting farmers of different ethnicity is as important as visiting different ecogeographic regions.

Minimal data to be recorded when collecting germplasm should describe country, lower-level administrative units, locality, latitude, longitude, altitude, collector number, type of material (seed, vegetative, pollen, in vitro material), improvement status (wild, weedy, landrace), abundance, morphological description of the accession, and habitat. Additional data that may be collected include slope, aspect, landform, and various descriptors for soil, drainage, and vegetation. Such basic data collected in the field have been referred to as passport data (as used elsewhere in this volume). The more data collected the better, but the need for data must be balanced with time constraints and the need to visit additional sites. Some descriptors applying only to landraces include farmer name, cultural methods used by farmers, length and time of growing season, history of landrace, and traits perceived by the farmer and other users. Herbarium vouchers are also needed to document the collection, with enough duplicates to ensure that sets are left in the country and others left in recognized institutions upon return home. Collections ultimately are studied by a wide array of broadly defined prebreeding studies to guide the
breeders in their use, as taxonomy, diversity screening, or resistance evaluations. Such studies vastly increase the value of collections, and can be greatly aided by the careful collection of the field data previously described.

CONCLUSION

Most agreements stipulate the deposition of duplicate germplasm and herbarium samples in the country, although others may state otherwise (e.g., collectors may be allowed to leave with all germplasm if the host country is provided with a sample of the first germplasm increase). Successful passage of samples through quarantine to the germplasm station is greatly facilitated by cleaning and processing samples properly. For example, herbarium specimens and fruits often harbor adult insects or larvae, so proper fumigation and seed extraction are crucial to successful introductions. Notes taken in the field are often scanty; it is best to write a complete report soon after the expedition, before facts are forgotten. Well-planned and conducted expeditions often merit publication in peer-reviewed crop-specific journals or journals devoted to germplasm collections and evaluations, such as Genetic Resources Newsletter, FAO. Such publication makes results of an expedition accessible to the world germplasm community. When published with cooperators, it generates goodwill and opens doors for continued collaboration.

Germplasm Collections: Regeneration in Maintenance

Linda Pollak
Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

When seed samples are collected from populations and saved in a germplasm bank, they are maintained as separate accessions (entries) along with the passport data gathered during collection. When the seed viability decreases or supply falls short due to inability to meet user demand, regeneration is necessary. Vegetatively propagated plants have special problems of regeneration. The goal of regeneration is to preserve the genetic variability that existed in the population when it was collected.

QUALITY CONTROL MAINTENANCE OF SEED-PROPAGATED COLLECTIONS

Allard[1] gives four primary reasons why genetic variability changes during maintenance or storage: differential survival rate during maintenance, selection during regeneration, outcrossing with other accessions, and genetic drift. There are substantial differences in the ability of different genotypes within a species to survive in storage, drastically altering the genetic composition of an entry.

During regeneration, selection can take place even under conditions designed to maximize survival and minimize selection, and can bring about substantial change in genetic composition.[1] Over several cycles of regeneration, the entry could have little resemblance to the parent collected in nature. Many of the reasons why unintended selection takes place are environmental and are a result of regenerating accessions in an environment to which they are not adapted.

In outcrossing species, outcrossing with other entries can be a problem when pollination is not carefully controlled.[1] Outcrossing can also be a problem with inbreeding species (self-pollinators) where pollination is not normally controlled, because a small percentage of outcrossing can still occur in self-pollinators. This can be a problem when regenerating a very large collection, because the percentage of outcrossing can vary among accessions. It is not normally feasible to control pollination in self-pollinators because it is usually difficult and time consuming, and therefore expensive.

When sample size of an entry is small (i.e., few seeds), there can be drift toward fixation of alleles (loss of variability) during regeneration in both outcrossing and inbreeding species.[1] Fixation is largely independent of selective value, so many entries become fixed for deleterious alleles and are difficult to maintain. If the collection is large, however, genetic variability can be preserved because genes will become fixed randomly in entries.

UNINTENDED SELECTION WHILE REGENERATING UNADAPTED ACCESSIONS

One needs to be aware of the breeding system of the species being regenerated regarding overdominance, additive effects of blocks of genes, level of ploidy and genome structure (auto or allopolyploidy), vegetative behavior (annual or perennial), and competitive ability at various stages of development.[3] These characteristics are interactive so that the population can flexibly react to selective pressure in its natural environment. Therefore, all elements of this system have to be taken into account carefully when we preserve and regenerate the population in order to avoid inadvertent changes in the genetic makeup, which would result in permanent loss of some variability.

Transfer of ecotypes from original conditions to a collection center disturbs normal selection pressures.[2] When artificial cross-pollinating is necessary, plant density needs to be optimal, and limiting factors of the environment not present in the area from which the population derives must be controlled (including abnormal frost, drought, heat, and pathogenic attack).

The primary environmental factors influencing flowering are day length (photoperiod) and temperature,[3] In photoperiod-sensitive species, such as maize, photoperiod determines the location where successful regeneration of short-day accessions can take place. Response to day length is also influenced by temperature. Most plants have critical minimum and maximum temperatures, and temperature’s effect on floral initiation and development is highly variable, even within species. Many species exhibit some form of dormancy.[4] For example, some winter annuals and biennials require exposure to low temperatures before reproductive development can be initiated. Multiple planting dates while regenerating may restrict subpopulation segregation by day length or maturity, and thus maintain population outcrossing.
For wind-pollinated species problems can arise from a change in weather conditions.\textsuperscript{2} Pollen shedding is dependent on temperature, humidity, day length, etc. Under other climatic environments it could be reduced, and self-pollination would increase abnormally.

Adequate soil moisture is necessary for growing vigorous plants with minimal flower and seed abortion.\textsuperscript{3} Moisture stress can reduce seed production if the stress occurs during flowering and early seed filling. Moisture stress can also influence seed set of species that develop their fruit below ground. Maturity can be hastened by reducing available water toward the end of the growing season. Relative humidity is important at pollinating, but there is an upper limit above which pollen clumping and disease infections can occur. Successful flowering and seed set occur when soil fertility is maintained at a level that will produce healthy green plants.\textsuperscript{3} However, some plants have special nutrient requirements for seed development.

The following examples illustrate what can happen when accessions are regenerated in an environment without the natural pressures that occur in their environment of adaptation.\textsuperscript{2} In one example, insect pollinators have specific habits that allow pollination of plants normally pollinated by the insects. When transferring these plant populations we also have to consider transferring their original population of pollinators.\textsuperscript{2} There can be drastic consequences on the plant progeny when, after transfer to new conditions, the plant population does not have the proper pollinator. The problem can be alleviated by enclosing the regenerated population in screened cages with the appropriate insect, if it is available.\textsuperscript{4} Another example occurs in tropical grain crops or forages, where there are species complexes consisting of wild and cultivated varieties that under coevolution by permanent exchange of genic flow.\textsuperscript{2} Weeds forms can give variability and fitness to cultivated forms, or compete in eliminating weaker phenotypes. Weeds contribute as pollinators but escape harvest, so crop collections do not include the specific weed population. After regeneration of these accessions, a bias occurs in the reproduced cultivar if the weed pollinator is not available.

Populations also coexist with an agricultural system of specific biological, chemical, and physical environments.\textsuperscript{2} There is a negative correlation between the sophisticated control system in the most intensive agricultural systems and the genetic diversity of the plant. When regenerating populations under management techniques that optimize crop production from an economic point of view, there may be effects causing reduced diversity. Thus the agricultural system must also travel with the population.

### Changes in Allele Frequency

Allelic frequency is the percentage of a particular allele at a given locus in a population gene pool, considering all alleles at that locus. While regenerating an accession, it is very important to maintain the frequency of alleles so that rare alleles are not lost. It is less important to preserve a representative sample of the target species than to preserve at least one copy of each of the different alleles.\textsuperscript{5} The common alleles are of far greater interest to plant breeders, but rare alleles may be important for special uses. Losses of samples and alleles can be controlled by judicious management of the collection and reduced to acceptable levels.

Allelic diversity in accessions decays during regeneration, based on three variables: the size of the population grown for regeneration; the mating system; and the variation in the number of gametes per plant.\textsuperscript{6} Procedures for maintaining accessions should be chosen based on optimizing these variables within the limited amount of resources available. Population size is the most important variable, but if populations of the needed size are not practical due to a large number of accessions that need to be maintained, the other two variables become more important.

Yonezawa et al.\textsuperscript{6} found that a single-seed-type regeneration (each plant leaves one progeny) gave the largest effective population size in regenerating seed of moderately or highly selfing species, whereas a biparental regeneration (plants are pollinated in pairs with one offspring left from each of the paired plants) gave the largest effective size for outcrossing species. However, differences between the systems were not appreciably large unless the accessions were regenerated over 10 or more cycles with 50 or fewer plants. They suggest that a single-seed system combined with selfing may be the most effective procedure for regenerating the seed of outcrossing species if the species is self-compatible and sufficiently tolerant to inbreeding depression.

Whenever possible, regeneration procedures should control the number of pollen parents through controlled hand pollination and control the number of female parent gametes by harvesting equal numbers of kernels from each seed plant.\textsuperscript{7} When pollen and seed parents are controlled during regeneration the effective population size is twice the size of the original population. Cossa et al.\textsuperscript{7} recommended a sample size of 150–350 maize plants to capture alleles at frequencies of 0.03–0.05 or higher in each of 150 loci, with a 90–95\% probability.

Some studies show that genetic drift is not a large problem. In comparing three methods of pollination (plant to plant, chain crossing, and mixing pollen) there were no significant differences among frequencies observed using seeds of maize accessions with floury and flint endosperm characteristics in frequencies of 0.97 and 0.03, respectively.\textsuperscript{8} Wheat microsatellite markers were used to analyze eight bulks of seeds stored more than 50 years in a seed reference collection at room temperature and regenerated up to 24 times.\textsuperscript{9} No contamination
due to foreign pollen or incorrect handling was discovered. In one accession genetic drift was observed, and in another heterogeneity for two markers was maintained. This study showed microsatellites to be a simple and reliable marker system for the verification of the integrity and genetic stability of gene bank accessions. Biotechnology methods have primarily been of benefit for crops difficult to maintain, however, such as those requiring vegetative propagation and those with recalcitrant seeds that cannot be dried to low levels for optimum storage.\[10\]

**Vegetatively Propagated Plants**

Vegetatively propagated germplasm is the most difficult and expensive to regenerate, and generally requires considerable space.\[4\] Although some of these crops are sexually fertile, it is often not convenient to propagate them commercially from seed because of high levels of heterozygosity, and because breeders require uniform clones. Many are sterile or polyploids, or have reduced fertility.

Vegetative organs are short lived and deteriorate rapidly after harvest, unless stored in ideal storage conditions.\[11\] Annual regeneration is costly, and there is danger of disease infection. It is extremely difficult to keep vegetatively propagated plants free from viruses, which leads to degeneration of clonal stocks. Because of these special problems, tissue culture or in vitro techniques are used.\[11\] Keeping the cultures in ultra-low temperatures opens the possibility of storing the germplasm indefinitely. Tissue culture has a major advantage, in that a large number of genotypes can be stored in a relatively small area at a fraction of the cost of growing the material in the field. The two major problems with using tissue culture are high levels of somaclonal variation, which occurs when tissue is regenerated into seedlings, and the limited length of storage time before regeneration is required. Improved tissue culture techniques are leading to lower somaclonal variation levels, and work is proceeding on cryopreservation that will allow tissue to be preserved for long periods.\[10\]

**Cost-Benefit Ratios of Regeneration**

The labor requirement of regeneration is reduced as storage conditions improve.\[11\] If materials are extremely similar they can be combined as more is learned about them. We should aim to conserve sufficient stocks of each species to saturate the breeder’s capacity to evaluate and utilize the conserved germplasm, both now and in the future.\[5\] Thus, evaluation and utilization should be the major limiting factors in germplasm conservation.

Germlasm Enhancement Through Mutation Techniques

Karin Nichterlein
Miroslaw Maluszynski
Joint FAO/IAEA Division of Nuclear Techniques in Food and Agriculture,
Vienna, Austria

INTRODUCTION

Most of the available genetic variation used in crop improvement programs, existing in germplasm collections of cultivars, landraces, breeding lines, and related wild species, has been generated over time through spontaneous mutations and hybridization. When existing plant genetic resources lack the desired trait in a compatible accession, it is often possible to generate it by mutations. Because spontaneous mutations occur with relatively low frequency, mutation techniques are used to change one or two characters of an otherwise well-adapted cultivar or for the domestication of wild species. Mutagenic agents cause random changes in the nuclear or cytoplasmic DNA resulting in gene (point), chromosomal, genomic, or extranuclear mutations. Most induced mutations are recessive and deleterious. However, when combined with an efficient screening for desired variation, induced mutations have contributed significantly to crop improvement and, in some cases, have made a considerable impact on the productivity of a particular crop. Chemical, radiation, and insertional mutageneses are also used in genomic research for assessing gene function through induction of loss-of-function mutations.

INDUCED MUTATIONS IN ENHANCEMENT OF SEED AND VEGETATIVELY PROPAGATED CROPS

Mutagenesis has been known since about 1920 when Muller discovered increased mutation rate in *Drosophila* after X-ray treatment and Stadler found a similar effect in plants. Currently, most frequently used physical mutagens are gamma rays, fast and thermal neutrons, heavy particles, and cosmic rays. Several chemicals, such as ethyl methanesulfonate (EMS), sodium azide (NaN₃), N-methyl-N-nitroso urea (MNH= MNU), N-ethyl-N-nitroso urea (ENH= ENU), and ethylene-imine (EI), have been identified as mutagenic and used for mutation induction. Gustafsson[1] in Sweden and Freisleben and Lein[2] in Germany introduced induced mutations as a tool in plant breeding. Research on the theoretical basis of mutagenesis in plants has been conducted since the 1940s with major activities in the 1960s. As a result, the methodological principles on the use of various mutation techniques to create and select desired genetic diversity were formulated and published as a guideline for plant breeders and scientists in the *Manual on Mutation Breeding*.[3] The transfer of mutation methodologies developed for seed and vegetatively propagated crops to national plant breeding programs around the world led to the release of a great number of improved crop cultivars. Today, the FAO/IAEA Mutant Varieties Database includes 2252 officially registered mutant cultivars of more than 160 species. Over 170 new cultivars were released between 1995 and 2000. The majority of the accessions (75%) are of crops and 25% ornamental and decorative plants.[4] Of the 2252 total accessions, 70.4% were released as direct mutants, i.e., through direct multiplication of selected mutants, and 20.6% through crosses with a mutant. Radiation was most frequently used (89%) for directly developed mutant cultivars, whereas the use of chemical mutagenesis was relatively infrequent. Gamma-ray treatment was employed for the development of 64.5% of the radiation-induced mutant cultivars followed by X-ray treatment (22.0%), chronic gamma-ray treatment (4.3%), fast neutrons (3.4%), and thermal neutrons (1.6%). Most crop mutant cultivars have been released in seed-propagated species (1603), with the majority in cereals and legumes, followed by industrial, vegetables, oilseeds, and other crops. In rice alone, 434 mutant cultivars have been released with improved characters, especially semi-dwarfness and earliness. Only 97 out of 1700 crop cultivars are vegetatively propagated species, among which fruit crops predominate.[4]

The general procedures for using induced mutations in seed-propagated species are rather simple and have remained valid for the last 60 years[3,5] (see Fig. 1). Mainly dormant seeds of the so-called parent variety (M₀ generation) are treated with mutagens. Pollen treatment is used only in few species such as maize.[6] As a result of the mutagenic treatment, genes can be changed to another allelic form, and mutagenized cells of the M₁
seeds become heterozygotic. Mutations are single-cell events, leading to plants having both nonmutated and mutated cells (chimerism). M₁ plants grown from mutagenized seeds produce seeds of the M₂ generation. The M₂ generation segregates for mutated traits. Very often, a deviation from the expected segregation ratio can be observed because of chimerism of the M₁ plants. Only mutations transferred into gametes are present in the next generation. Selection of mutants starts in the M₂ generation for traits that can be easily identified on a single plant basis. Selection continues in the M₃ generation, where further segregation appears. For traits that can be selected only on a row basis, selection will start in M₃. The procedure of selecting and handling mutants focuses on the separation of mutated genes from undesirable or even deleterious mutations at other loci. Both the chimeric structure of the M₁ plants and the existence of simultaneous, unwanted mutations make it necessary to examine large M₂ and M₃ populations to pick up a desired mutant. Fast selection methods facilitate the screening of large mutated populations. Selfing and backcrossing of mutants are often required to develop true-to-type mutant lines before they are multiplied and evaluated in multilocation trials or used for crosses.

Because doubled-haploid (DH) techniques became routine tools in breeding, their combination with induced mutations, by using M₁ plants as donor plants for haploid cells (treatment before meiosis) or by mutagenizing cultures of haploid cells (treatment after meiosis), allows the immediate detection of recessive DH mutants. If a selection agent is available, screening can be performed at

Fig. 1 Mutation techniques for the improvement of seed-propagated plants. (From Ref. [7].)
the cell or embryo level on a large mutant population in vitro.\[7\] Mutation induction protocols for microspore cultures have been developed for barley and oilseed rape and were successfully applied to produce herbicide-tolerant mutants and mutants with altered fatty acid composition of the seed oil.

In vegetatively propagated crops, a mutated cell of the meristematic tissues (bud, shoot apex) develops into a sectorial chimera. Before a desired mutated trait can be detected and screened, the mutated sector must develop into a selectable size such as a branch or shoot. The mutagenized shoot is called \(M_1V_1\) generation, from which the \(M_1V_2\) shoots develop. The new shoot from \(M_1V_2\) is called \(M_1V_3\) and so on. The percentage of chimerism for desired traits should start only in or after the \(M_1V_4\) generation. Progress in plant tissue culture of some species made it possible to mutagenize cells and tissues instead of cuttings. The advantages of using in vitro cultures are: 1) relatively uniform and large population of cells in the small size explant, enabling the irradiation of many cells; 2) disease-free material; 3) separation of mutated sectors in a short time; and 4) possibility for in vitro selection.\[8\] During the last two decades, commercial breeding companies routinely created new variations in flower color and morphology, leaf traits, and growth habit through induced mutations.\[9\] In fruits, mutation techniques have been used to induce compactness, early maturity, and improved fruit quality in apple, disease resistance in pear, compactness and self-incompatibility in cherry, seedlessness and red fruit color in citrus, and early maturity.\[10,11\]

**ECONOMIC IMPACT OF INDUCED MUTANTS**

**Semidwarfness**

Mutation techniques have been used as a simple and rapid tool to obtain semidwarf cultivars of cereals without changing other desired characters, such as adaptability, grain quality, and consumer preference. In rice, the mutant cultivars “Reimei” in Japan and “Calrose 76” in California have been widely used as major gene sources for modern semidwarf japonica-type cultivars in these countries, and mutant “IRAT 13” was developed in France for breeding semidwarf upland rice in Africa and South America.\[12,13\] In barley, two radiation-induced mutant cultivars “Golden Promise” and “Diamant,” both semidwarf and released in the 1960s, were used for the development of a wide range of barley cultivars throughout Europe: 17 Golden-Promise-derived cultivars were released in United Kingdom and 112 Diamant-derived cultivars were released in former Czechoslovakia and various European countries.\[14\] In durum wheat, mutants and their derivates with improved straw architecture, lodging resistance, and high yielding ability became leading cultivars in Italy.\[14\]

**Disease Resistance**

Various mutant cultivars of chickpea with high yield and disease resistance were released in Pakistan, from which “CM-72” resistant to Ascochyta blight is still the major chickpea cultivar in that country. A black spot disease-resistant mutant cultivar of Japanese pear was released as “Gold Nijiseiki” in Japan with high economic impact. Two mutant cultivars of peppermint tolerant to Verticillium wilt which were released as “Todd’s Mitcham” and “Murray Mitcham” in the 1970s are still recommended to control Verticillium wilt in United States, where 90% of the world’s peppermint oil is produced.\[15\]

**Quality**

Red grapefruit is important for export in Texas, and mutant cultivars with deep red fruit color were released after radiation treatment: “Star Ruby” released in 1970 and “Rio Red” released in 1984. The fruits of both cultivars are sold under the trademark “Rio Star.” In Texas, Rio Star grapefruit is currently grown on 7300 ha, which is 75% of the state’s total grapefruit production area. In sunflower, a mutant with increased oleic acid content was developed by chemical mutagenesis and officially released in 1977 in the former USSR. The mutated allele was used to develop sunflower cultivars, which are now widely grown in the United States for the production of more stable frying oil.\[15\]

**CONCLUSION**

Induced mutations alone or in combination with tissue culture techniques offer plant breeders and geneticists an efficient tool to improve specific traits of both seed and vegetatively propagated crops. Selected mutants can be used for direct multiplication and release as new improved cultivars or in crossbreeding and, recently, for genomic research. In each case, the use of mutation techniques will depend on the specific objectives and the plant species. For the improvement of vegetatively propagated crops, the combination of in vitro and mutation techniques seems to be very suitable. The use of doubled-haploids in combination with induced mutations allows obtaining rapidly desired genotypes in a homozygous state in all seed-propagated crops, for which routine doubled-haploid techniques exist.

Germplasm Maintenance

Henry L. Shands
USDA–ARS National Center for Genetic Resources Preservation, Fort Collins, Colorado, U.S.A.

INTRODUCTION

The apparently mundane task of maintaining germplasm for a genebank is anything but mundane. Huge responsibilities are incumbent upon all those involved in the processing of germplasm, from acquisition to distribution. Scientists expect a high-quality and adequately documented product. To ensure quality in germination, freedom from disease, and adequate documentation, managers must examine all aspects of management, from initial receipt of seed to storage conditions.\[1\]

SOURCE OF GERMPLASM

Sites receiving germplasm must review the process through which they received it because authenticity is essential. Plant collecting is most easily documented through direct collectors\[2\] using Global Positioning System (GPS) locators and herbarium specimens. When it is received from another genebank’s collection, there may be gaps in the existing information, especially if the donor genebank is not the original source. If there are many points of handling between field source and genebank, there are more chances for errors in the documentation and integrity of the material. This is especially true if the sample has had multiple growouts since being acquired. End users must assess the source and determine their risk in data and germplasm accuracy. Maintenance of a nonoriginal source of germplasm is only as good as the many intervening waypoints.

Resource Documentation

If the material is not collected first-hand, documentation is often absent, inaccurate, or deficient. Most samples acquired through exchanges include little information provided with the sample.\[3\] For some end users, this is a minor omission but for others, it is of serious concern. Breeders screening for a specific trait will evaluate the sample for that trait while assessing other virtues. To the extent possible, those data will be put into the database. Curators will assess all regular passport data characters and qualities and document them under their growout conditions to confirm and compare with any original passport data. The Food and Agriculture Organization of the United Nations (FAO) International Treaty on Plant Genetic Resources\[4\] requires that data be supplied to the requester. If data are not available, however, the requirement is hollow.

Field Growouts of Seed Crops

For the curator to properly maintain germplasm, sufficient critical data must be provided relative to the initial sample. Wild relatives of crop plants may be uniquely restricted to a specific point of origin but collectors try to collect many different samples throughout an area. A landrace would likely be more variable than a bred variety.

If a landrace acquisition is not the original sample, the curator must assess what population size and environmental biases have already occurred or been introduced. A recommended population size is dependent on numerous factors, including pollination method (selfing or outcrossing), heterogeneity of population, and goals of the curator to purify the sample or retain any heterogeneity or heterozygosity.\[5\]

If the sample has been regenerated under curator conditions (in contrast to in a farmer’s field), how many plants were grown and how were they pollinated? Unknown contamination from foreign pollen of like or compatible species is a concern to curators. To maintain the genetic integrity of the sample, the curator must take measures such as maintaining appropriate isolation distances or bagging to prevent contamination. The isolation distance is dependent on method of pollination (whether windblown or insect commuted), flowering type (whether open or closed, self or cross-pollinated), and, for some species, whether self-compatible or not. If pollination is carried out by hand, isolation distance is immaterial but some of the other factors remain critical.

If the material is from a tropical or subtropical environment, what biases have been or are being introduced...
by growing it in a temperate zone? When it is grown outside its normal eco-zone the population will likely be biased due to a truncated flowering period. Photoperiod-induced late flowering and subsequent seed set and seed development may be impaired and not represented in the harvest sample. The flowering date of the next population may thus be biased to be earlier, and the population may lose genes and traits physically associated with linkage groups containing flowering factors.

Some concern is raised about maintaining base collection samples free from gene constructs of genetically modified organisms (GMOs). Where regeneration occurs in areas where commercial GMO crops are grown, adventitious GMOs may result from cross-pollination. When base collection supplies are replaced by regenerated samples that possibly contain GMOs, notation to database records should be made. As with any contamination of the base sample, future regenerations will likely further deviate from the original description. The deviation will reflect any selective advantage of the GMO even if the regeneration site is removed from areas of GMO crops. Field collections of non-GMO clonally propagated crops would not normally be affected by the presence of new fields of GMO cultivars of the same species, or be affected by the same issues as seed crops as long as their reproduction is through the somatic buds of the original clone or its sports. However, seed sources would likely be affected.

**Field, Laboratory, and Greenhouse Maintenance**

Regeneration is one of the most costly operations for a genebank. This cost is not only in time and money but also in the risks involved. In all aspects of genebank management, clean seed/propagule practices must be followed expressly in seed room and laboratory preparation, in hand or mechanical planting, in hand bagging and pollination, and in harvest and seed processing techniques. Precision of accession and location information can be assisted with bar coding, but labels must be carefully applied. Mixtures from improper human procedure are as problematical as those from weather-related events. Torrential rains—whether alone, of associated with tropical storms, or coupled with tornadoes’ destructive winds—can move or destroy plants in the field, greenhouse, or laboratory. Maps of exact plantings should be safely stored for reference. Maps of clonal orchards are critical to reconstructing locations of individual plants or trees. Whatever the causal event for the mechanical mixture of seed, propagules, pollen, or plants, the result is the same—an inferior product to deliver to future generations. Preventive measures should be taken to minimize the risk of mixture and loss of genetic purity at all steps.

**GENETIC STOCK MAINTENANCE**

Not all germplasm is varietal material. Genetic stocks as a group include various gene mutations, chromosomal aberrations (such as translocations, additions/deletions, and inversions), and even increases or decreases in levels of ploidy of one or more of the chromosomes or whole chromosome sets. For most of these stocks, some genetic or cytogenetic analysis must be made of the resultant progeny to confirm the changes contained therein. A growout test is usually necessary to confirm the presence of a lethal mutant that must be maintained in a heterozygous condition with its allele. In all cases, the subsequent generation is analyzed to validate the genetic constitution of the progeny of the original regeneration. One must be careful not to expend valuable seeds in needless growouts. Also, a competent analysis is often required by a skilled scientist. Seed distribution is often limited to a few seeds due to their unique nature and cost. Genetic stocks are thus found mostly at special stock centers where the necessary expertise is available to maintain them. The same stock centers may also maintain the related wild relatives used in improving the crop. Scientists will often conduct interspecific and intergeneric crosses to move potentially useful alien genes and chromosomes into the cultivated form. This differs from the GMO issue discussed earlier because the generations subsequent to the crosses are subject to natural chromosome rejection, and few plants survive or lead to useful crop plants. The process is quite random—more in the realm of research than in the realm of contamination, as in the case of GMO field crops.

**Storage of Germplasm**

Storage is often the most cost-effective process in a genebank’s operation. Proper storage helps abate the high cost of regeneration and risk of loss of genetic integrity. Seed storage protocols for any seed crop begin at the time of pollination when procedures are put in place to assure accuracy of bagging notation. Insecticides are often dusted in the bags to reduce loss to predator insects that find the warm, moist environment enticing for feeding and reproduction. Seed maturity and drydown are important, so harvest must be made timely and seeds must be dried to remove excess moisture. Overheating in dryers and stacking in greenhouses without aeration or
elsewhere where rodents and other animals can do damage is obviously poor management. Once at the genebank, the seed material must be dehydrated through a combination of heat and dehumidification to reach optimum seed storage moisture.\cite{11,12} The moisture level is critical prior to placing seed in sealed foil bags or in liquid nitrogen vapor (cryopreservation). Data are evolving to suggest that long-term storage in liquid nitrogen vapor has merit over the conventional 20°C in extending seed life (Walters, personal communication). In some cases too little moisture will result in damage in storage.\cite{12} Data are available for many seed crops showing that lipids are a critical determinant of optimum seed storage moisture\cite{10,12} and that lipids influence aging kinetics\cite{10,13} and cell damage during cryopreservation.\cite{14}

Clonally propagated material in tissue culture must be carefully managed to reduce transfers and opportunity for somatic mutation.\cite{15} Cool storage and experimentation with culture media to extend storage life before transfer are essential. Cryopreservation for vegetative tissue of a limited number of species has only begun, and new protocols are evolving, giving hope that life expectancy can be improved and samples stored for long periods of time.\cite{15,16}

Although DNA storage has been given considerable discussion, there is little evidence that it will play a large role in genebank storage. It obviously will play a role in helping to validate genetic change and to elucidate individual’s genetic makeup for many purposes in the future.

**CONCLUSION**

Germplasm maintenance requires implementation of many pieces of information, careful techniques of propagation, and rigidly employed laboratory-type sanitation for stocks and their environment. Anything less subjects the germplasm to loss of genetic integrity and truism, and incorporates imperfections to pass on to future generations.

Germplasm: International and National Centers

Jonathan Robinson
Murthi Anishetty
Food and Agriculture Organization of the United Nations, Rome, Italy

INTRODUCTION

It is estimated that ex situ plant germplasm collections comprise six million accessions, over half of which represent base collections, kept solely for conservation. The remainder are active, working collections available for distribution and use by plant breeders and researchers. One third of the total number of accessions is thought to be unique. The 11 genebanks of the Consultative Group on International Agricultural Research (CGIAR) and International Agricultural Research Centers (IARCs) together house major collections of accessions (ca. 600,000). The rest are conserved in about 1300 regional and national genebanks. The CGIAR collections have been built up over 25 years and, following agreements signed in 1994, are held in trust for the world community under the intergovernmental authority of the Food and Agriculture Organization of the United Nations (FAO).

DISCUSSION

Most plant germplasm is conserved as seeds, but approximately 500,000 accessions, many of which represent fruit trees, are maintained in field genebanks. An additional 40,000 accessions are conserved in vitro through cryopreservation or tissue culture. Botanical gardens, arboreta, and herbaria are also important centers for plant germplasm conservation. There are approximately 1500 such centers spread around the globe. The majority are located in Europe, the Commonwealth of Independent States, and the United States. A little over 10% are privately owned. Germplasm seedbanks are also maintained by 150 botanical gardens. About half the botanical gardens conserve germplasm of ornamental species, crop relatives, medicinal plants, and forest trees.

International and regional centers conserve broad ranges of plant germplasm derived from diverse locations. Many national germplasm centers conserve mainly indigenous material, whereas others, including those in Australia, the United Kingdom, and United States for example, conserve mainly imported germplasm. National genebanks such as the N.I. Vavilov All-Russian Research Institute for Plant Industry (VIR) in Saint Petersburg, Russia, maintain accessions collected from around the world and more resemble international centers than national ones. The Institute of Plant Genetics and Crop Plant Research (IPK) at Gatersleben, Germany, is another such institute that houses large and diverse collections of crop germplasm. Whereas the international and regional centers for plant germplasm are generally able to conserve collections under optimal conditions, the state of national collections varies enormously. The number of unique accessions is often difficult to determine, as duplication—deliberate as well as unintentional—is often not easy to gauge. Developed countries invariably have seed and field genebanks and botanical gardens, but many developing nations do not. However, substantial germplasm collections do exist in some developing countries, including Brazil, China, Ethiopia, and India. India, Indonesia, and Sri Lanka, moreover, have among the best maintained tropical botanical gardens in the world, at Calcutta, Bogor, and Kandy, respectively.

Useful information on genebanks and their operations is available in several general texts.[1–4]

INTERNATIONAL CENTERS

The CGIAR centers have mandates to breed and research a limited number of crop species, including most of the major staples of the developing world; their genebanks consequently house germplasm geared toward those ends. Several of the collections—including CIMMYT’s wheat (Triticum spp.), IRRI’s rice (Oryza spp.), CIAT’s bean (Phaseolus spp.) and cassava (Manihot spp.), and ICRI-SAT’s chickpea (Cicer arietinum) and pigeon pea (Cajanus cajan)—represent the world’s largest ex situ collections of those crops. Detailed information on international agricultural research center holdings is available from the System-wide Information Network for Genetic Resources (SINGER) database.[5] These data are summarized in Table 1.
There are five principal regional centers for plant germplasm. The Asian Vegetable Research and Development Center (AVRDC) is located in Taiwan and holds over 47,000 accessions, concentrating on tomato (*Lycopersicon esculentum*), pepper (*Capsicum* spp.), soybean (*Glycine* spp.), and mung bean (*Vigna* spp.) germplasm. It is one of the world’s largest genebanks for vegetable species. The Centro Agronómico Tropical de Investigación y Enseñanza (CATIE) in Costa Rica conserves more than 35,000 accessions of curcurbits, peppers, beans, coffee (*Coffea* spp.), and cocoa (*Theobroma* spp.) in seedbanks and in decentralized field genebanks. Large ranges of temperate fruit and berry crops are maintained in the field genebanks of the Nordic Gene Bank (NGB), headquartered in Sweden. In total it manages more than 27,000 accessions, including vegetable, root, oil, and pulse crops. The Southern African Development Community (SADC) has a plant genetic resources center in Zambia that contains approximately 5000 germplasm accessions, representing collections and duplicate collections of southern African national collections. Last, the Arab Center for the Studies of Arid Zones and Dry Lands (ACSAD) in Syria has a sizeable collection of fruit trees from West Asia and North Africa. Other regional genebanks are being developed. For instance, a taro (*Colocasia* spp.) genebank is being established in Fiji that will serve the 22 member states of the South Pacific Community.

**REGIONAL CENTERS**

There are five principal regional centers for plant germplasm. The Asian Vegetable Research and Development Center (AVRDC) is located in Taiwan and holds over 47,000 accessions, concentrating on tomato (*Lycopersicon esculentum*), pepper (*Capsicum* spp.), soybean (*Glycine* spp.), and mung bean (*Vigna* spp.) germplasm. It is one of the world’s largest genebanks for vegetable species. The Centro Agronómico Tropical de Investigación y Enseñanza (CATIE) in Costa Rica conserves more than 35,000 accessions of curcurbits, peppers, beans, coffee (*Coffea* spp.), and cocoa (*Theobroma* spp.) in seedbanks and in decentralized field genebanks. Large ranges of temperate fruit and berry crops are maintained in the field genebanks of the Nordic Gene Bank (NGB), headquartered in Sweden. In total it manages more than 27,000 accessions, including vegetable, root, oil, and pulse crops. The Southern African Development Community (SADC) has a plant genetic resources center in Zambia that contains approximately 5000 germplasm accessions, representing collections and duplicate collections of southern African national collections. Last, the Arab Center for the Studies of Arid Zones and Dry Lands (ACSAD) in Syria has a sizeable collection of fruit trees from West Asia and North Africa. Other regional genebanks are being developed. For instance, a taro (*Colocasia* spp.) genebank is being established in Fiji that will serve the 22 member states of the South Pacific Community.
the South Pacific Commission. There is also a multiple-site International Coconut (Cocos nucifera) Genebank hosted by Brazil, Côte d'Ivoire, India, Indonesia, and Papua New Guinea.

NATIONAL CENTERS

National genebanks comprise a range of institutions administered by governments, universities, nongovernment organizations (NGOs), and the private sector. Most countries in Europe have established genebanks. Many of those genebanks contain working collections, but university genebanks, for example, often hold important collections of genetic stocks. The Royal Botanic Gardens at Kew in England have substantial living plant collections—including native and exotic species—at two sites. There is also a national reference collection of over seven million plant specimens (including 250,000 type specimens) and 20,000 seed accessions in the herbarium carpological collections. The Millennium Seed Bank is the largest seed bank in the world for wild plants and holds seed of more than 5000 species from 600 genera. The Russian national genebank, VIR, has vast germplasm collections of a range of crop species, including large collections of maize, Zea mays (18,000 accessions) and wheat (36,000) and the world’s largest potato (Solanum tuberosum) collection (8500 accessions). Some major genebank holdings for a range of crops are given in Table 2.

Africa has relatively few centers for plant germplasm that function effectively. Facilities are most advanced in Côte d’Ivoire, Ethiopia, Kenya, and Nigeria. However, more than 80% of oil palm (Elaeis guineensis) accessions are maintained in the Democratic Republic of the Congo, and Uganda has an important collection of banana (Musa spp.) germplasm (250 accessions). In the Near East, Turkey has one of the few facilities with long-term storage capacity, but genebanks in Iran, Israel, Pakistan, and Turkey operate at a high level. The Hebrew University of Jerusalem has an important sesame (Sesamum indicum) collection. Field genebanks in the Near East are quite numerous. Turkey has several field genebanks devoted to crops including fruit trees, olives (Olea europaea), and garlic (Allium sativum). In South Asia, the genebank facilities in India are the most advanced. The Indian Agricultural Research Institute, for example, has the world’s largest collection of maize germplasm (25,000 accessions) and the National Bureau of Plant Genetic Resources has the world’s second largest chickpea collection (ca. 15,000 accessions).

There are several major national collections of germplasm in the East Asia region, especially in China, Japan, and the Republic of Korea, as indicated in Table 2. Those collections include soybean, citrus, and sesame. In terms of total numbers of genebank accessions, China ranks second in the world (350,000) after the United States (555,000) and ahead of India (342,000). In Southeast Asia and the Pacific, Indonesia, Malaysia, the Philippines, and Thailand have important centers for germplasm conservation, including many important field genebank collections. Only two genebanks holding substantial numbers of accessions of banana and plantain germplasm are in the center of origin of the crop. These collections are in Papua New Guinea (The National Agricultural Research Institute), which has the highest number of unique banana/plantain accessions, and the Philippines (Davao National Crop Research and Development Center). The National Plant Genetic Resource Center of the Philippines holds the world base collections of several minor crops and duplicate collections of some Asian vegetables. Kebun Raya, the Indonesian botanical gardens at Bogor, were established in 1817 and now cover four sites and contain over 15,000 species of trees and plants. Oil palm was introduced into Southeast Asia in 1859 from plants grown there.

In the Americas, the United States and Canada have numerous large seed genebank and field genebank collections. Argentina, Brazil, Chile, Mexico, and Venezuela also have good long-term storage facilities. The two Brazilian agencies, Centro Nacional de Recursos Genéticos e Biotecnologia (CENARGEN) and Empresa Brasileira de Pesquisa Agropecuária (EMBRAPA), manage large collections of a range of crops including beans, cassava, cocoa, citrus, rice, and soybean. There are several major bean germplasm collections in Mexico. Honduras (Funda- ción Hondureña de Investigación Agrícola, FHIA) has a large and very important collection of 430 banana and plantain accessions. Cuba is relatively alone in having adequate facilities in the Caribbean, but Trinidad and Tobago holds a major cocoa germplasm collection (2300 accessions). The United States Department of Agriculture (USDA) Agricultural Research Service (ARS) has national plant germplasm collections at about 30 sites. The National Small Grains Collection (NSGC) at the University of Idaho, Aberdeen, has sizeable collections of wheat (>46,500); barley (ca. 27,000); oats, Avena sativa (21,000); rice (>17,000); rye, Secale cereale (>2000); triticale, X Triticosecale (ca. 2000); and Aegilops (>2000). The USDA, moreover, has a very important potato germplasm collection at Sturgeon Bay and a substantial fruit, nut, and horticultural crop germplasm collection in Corvallis, at Oregon State University (11,430 accessions representing 54 genera and 745 species). The National Seed Storage Laboratory is located in Fort Collins, Colorado, and is a base collection repository for 23,827 accessions representing 207 genera and 514 species. There are numerous other germplasm centers at the many agricultural universities in the United States, including a particularly important

CONCLUSION

The recently signed International Treaty on Plant Genetic Resources for Food and Agriculture, adopted by the thirty-first session of the FAO Conference (November, 2001) represents a legally binding international commitment to the improvement of the world’s key food and feed crops. The Treaty is based on a multilateral system of facilitated access and benefit sharing. This multilateral system covers plant genetic resources for food and agriculture, including a list of crops established according to the criteria of food security and interdependence. The list of crops covers species from 54 major crop genera, but excludes some genera of major importance, including Glycine, Arachis, and Elaeis. Also included are over 80 species of forages from 29 genera. It is anticipated that if there is unrestricted access to the listed genetic resources they will be better conserved for the future.

Although the germplasm in the genebanks of the developed world is generally well conserved, that in many of the developing countries is in a precarious position. Moreover, some germplasm collections—particularly field genebanks—are naturally vulnerable. Banana and taro collections are two examples prone to hurricane damage and disease, respectively. In addition, potentially important sources of wild relative germplasm grow in vulnerable ecosystems and environments, which are at risk of being lost. Through an initiative begun by the System-wide Genetic Resources Program of the CGIAR, termed the Global Conservation Trust, it is hoped to ensure that some of the most important and vulnerable germplasm collections in the world can be conserved for the well-being of humankind.

Glycolysis

Florencio E. Podesta
Universidad Nacional de Rosario, Rosario, Argentina

INTRODUCTION

Glycolysis is a universal metabolic route present in all living cells, at least in part. It is commonly defined as the catabolic pathway leading to the conversion of sugars into pyruvate.

\[
glucose + 2 \text{ADP} + 2 \text{Pi} + 2 \text{NAD} \\
\rightarrow 2 \text{pyruvate} + 2 \text{ATP} + 2 \text{NADH}
\]

As presented, this equation, which applies well to animal or yeast glycolysis, implies a simple, straight path of degradation from glucose to pyruvate. This assertion has become increasingly outdated, when applied to plants, by the vast amount of new information gathered within the past three decades of research.

DISTINCTIVE FEATURES OF PLANT GLYCOLYSIS

Research in the carbohydrate metabolism area has provided unequivocal information showing that plant glycolysis has distinctive features that encompass the existence of unique enzymes, the use of pyrophosphate instead of ATP as phosphate donor, and a different mode of regulation.[1–3] In plants, carbon may enter glycolysis from two pools: the hexose phosphate pool and the triose phosphate pool.[2] The first is fed by sucrose or starch degradation. The second pool is the result of hexose-phosphate degradation, photosynthetic carbon fixation, or the action of the oxidative pentose phosphate pathway.[2] Additionally, the presence of enzymes specific to plant glycolysis can change the final product and/or the ATP yield.[1] Having these facts in mind, it is easy to visualize that the glycolytic metabolism in plants is not a mere linear sequence of reactions leading from one substrate to a final product; on the contrary, the actual substrate and products will depend on the metabolic status of the plant tissue at that particular time.

Plant Glycolysis Is Compartmentalized

Unlike heterotrophic organisms, plants are able to synthesize hexoses through photosynthesis and thus do not depend on an external carbon source. In chloroplasts, carbon is fixed and transiently stored as starch. In nonphotosynthetic tissue, plastids also serve as carbon stores, using imported carbohydrate that comes in the form of sucrose. Thus, at least part of the glycolytic machinery has to be used in plastid carbon metabolism to degrade starch products and provide ATP, NADH, pyruvate for fatty acid synthesis, triose phosphates that are exported to the cytosol, and intermediates for secondary metabolism.[1]

Meanwhile, cytosolic glycolysis is the source of pyruvate for the tricarboxylic acid cycle, with the concomitant production of ATP and NADH. It also generates the carbon skeletons needed in N assimilation through associated anaerobic reactions and the PEP used in primary carbon fixation in crassulacean acid metabolism and C4 plants.[4] The plastid and cytosolic hexose-phosphate and triose-phosphate pools are connected through the Pi translocator of the inner plastid membrane.

It is of paramount importance to realize that glycolysis in plants goes far beyond being a merely catabolic metabolism designed to obtain energy and reductive power from hexoses. Its products serve as precursors for several anabolic pathways leading to the synthesis of amino acids, lipids, and other cell constituents. The separation of roles and operational timeframe among the cytosol and plastid carbon metabolism calls for different regulatory needs, and compartmentation provides a means of integrating different metabolic pathways with diverse control requirements.

THE OPERATION OF PLANT GLYCOLYSIS

Individual Reactions

Beyond a description of each of the reactions involved in glycolysis, this section presents a summary of the main features that characterize plant glycolysis and differentiate it from animal and yeast counterparts, offering an account of the recent knowledge regarding its particular chemistry and mode of regulation.

The first step of glycolysis consists of the phosphorylation of hexoses that will then enter the hexose phosphate pool (Fig. 1). Hexose phosphates are produced...
in the cytosol during degradation of sucrose by sucrose synthase and UDP glucose pyrophosphorylase. The action of invertase gives rise to hexoses, which are phosphorylated by a hexokinase. As in animal cells, plant hexokinase has also been reported to be bound to mitochondria.\(^2\) Cytosolic hexokinase has also been implicated in the sugar-sensing pathway that governs specific carbohydrate metabolism gene expression.\(^5\) Plastid hexokinase is used to phosphorylate glucose produced by amylolytic starch degradation, although its presence is not universal in all plants.

The hexose phosphate pool exists in a thermodynamic equilibrium maintained through phosphoglucomutase and phosphoglucoisomerase, which catalyze reversible reactions. The next step is where one of the crucial differences between animal and plant glycolysis surfaces. The phosphorylation of Fru-6-P in the cytosol can be achieved by two different enzymes: the classical PFK reaction using ATP, or the alternative reaction that uses PP\(_i\) as phosphoryl donor, catalyzed by the pyrophosphate-dependent PFK or PFP (Fig. 1).

The latter reaction is exclusive to the plant cytosol, and although it is also present in some bacteria and unicellular parasites it has not been found in animals or yeast.\(^1\) PFP, unlike PFK, catalyzes a reversible reaction, which is remarkable considering that the Fru-6-P/Fru-1,6-P\(_2\)
interconversion is a key regulatory step in glycolysis. The presence of PFP and the fact that PPi concentrations remain stable in the plant cytosol under a variety of conditions make this reaction a bypass to that catalyzed by PFK (and FBPase in the opposite direction), eliminating the use of one ATP molecule. Although its precise role in plant metabolism is not yet clearly defined, it could fulfill a role in the glycolytic breakdown of sugars under nutrient stress conditions. In certain CAM plants, where a massive flux of carbon through the glycolytic pathway is required, PFP activity can exceed PFK by an order of magnitude. Recent studies also hint at this enzyme being a potentially important target for glycolysis regulation.

Fru-1,6-P2 is converted to triose phosphates by aldolase. Plant aldolases, both cytosolic and plastidic, are structurally related class I aldolases. Although not a regulatory enzyme, aldolase plays an important role in photosynthesis control.

Upon interconversion of DHAP in Ga3P, the ATP-yielding phase of glycolysis starts (Fig. 1). Ga3P is oxidized to 1,3DPGA by GaPDH, which conserves the energy obtained from oxidation by a high-energy mixed anhydride between the phosphate and a carboxyl group. In this reaction, reductant is formed as a carboxyl group. In this reaction, reductant is formed as a carboxyl group. The PEP carboxylase and pyruvate kinase reactions are subject to a variety of regulatory mechanisms. Depending on the tissue, cytosolic pyruvate kinase is inhibited in a pH-dependent fashion by several tricarboxylic acid cycle intermediates, ATP and notably the amino acids Asp and Glu, linking glycolysis to N metabolism. Accordingly, plant PEP carboxylases are strongly feedback-inhibited by malate and activated by glucose-6-phosphate. This regulation is, in turn, modulated by a sophisticated signal transduction mechanism that affects the phosphorylation state of the enzyme, which is linked to the illumination state of the leaf and other signals. The reduction state of disulfide groups in glycolytic enzymes has also been implicated in regulation, as is the case for plastid and cytosolic GaPDH or PFP, which are activated by reduction.

GLYCOLYSIS AND CROP PRODUCTIVITY

Given the widespread impact of the glycolytic pathway in the general metabolism of plant cells, it is not surprising that an important effort is being conducted to fully understand its operation. The beneficial aspects of the potential manipulation of plant glycolysis are not restricted.
to higher crop yields in terms of total starch or sucrose produced; a change in the nutritional content of crop plants is also possible as a result of the cross talk with nitrogen and lipid metabolisms.

INTRODUCTION

Food production necessary to meet the growing demands of the world population is a critical issue today and will continue to be a concern in the future. One of the most important constraints on efficient food production is the ability to effectively manage weeds. If weeds are not managed, no food can be produced. Weeding crops has required more expenditure of energy and time than any other task. Historically, man has managed weeds by hand. Mechanical weed management began a new era in crop production efficiency. In the mid-20th century, the management of weeds with herbicides dramatically improved crop production efficiency. The next technological step in weed management is the development of herbicide-resistant crops.

TRANSGENES AND CROPS

The ability to transform plants by the introduction of selected genetic characteristics has dramatically changed the ability of plant breeders to improve agronomic crops. The first genetically modified (GM) crops contained transgenes that conferred resistance to herbicides, diseases, or insects. Commercial utilization of GM crops has increased to over 52 million ha worldwide with most of the increase occurring in the industrialized countries. However, proponents of biotechnology suggest that increases in yields and quality attributable to GM crops will also be critically important to developing countries.

The adoption of GM crops is thought by some to be environmentally benign or beneficial, but there is concern that there may be some undesirable impacts with commercial-scale GM crop production. The inclusion of transgenes that code for the Bacillus thuringiensis protein has resulted in reduced use of insecticides. Transgenes that result in glyphosate resistance in crops allow growers to use glyphosate for weed management. Glyphosate is suggested to be an environmentally safer herbicide. However, there are concerns that the inclusion of transgenes that code for protein may cause a hypoallergenic reaction in some people. Interestingly, there has not been a general societal consensus that reflects the attitude toward GM crops despite the unprecedented adoption of the technology by industrialized agriculture.

One of the most important and widely successful concepts resulting from transgene technology confers herbicide resistance (HR) to crops. However, herbicide resistance also has been introduced into crops with traditional breeding techniques. Herbicide-resistant maize (Zea mays), soybean (Glycine max), canola (Brassica napus), rice (Oryza sativa), and cotton (Gossypium hirsutum) are widely planted in North America, and HR sugar beets (Beta vulgaris) and wheat (Triticum aestivum) are likely to be introduced commercially in the near future. A primary benefit attributed to HR crops is the ability to use environmentally benign herbicides. Given the public concerns about herbicide use, this is an important consideration supporting the adoption of HR crops. Other benefits supporting the adoption of HR crops include selective herbicides where none were previously available, choices of cheaper herbicides, ease or simplicity of weed management, increased adoption of tillage practices that minimize soil erosion and improve soil quality, and the elimination of herbicide injury to crops.

Herbicides are the primary, if not sole tactic used to control weeds in most crops including HR crops. Farmers in the United States apply herbicides to more than 220 million crop acres at a cost of $6.6 billion. The adoption of HR crops will increase the emphasis on herbicidal weed control and undoubtedly focus on a few herbicides. This paper will report on the implications of HR crops on agriculture and review the implications of this technology on agroecosystems and the socioeconomic aspects of an agriculture that is based on HR technology.

WEED MANAGEMENT WITH HERBICIDE-RESISTANT CROPS

Fundamentally, weed management with HR crops is no different than using other selective herbicide technologies—a herbicide is applied to the crop, and the weeds are selectively controlled. The difference is how selectivity between crops and weeds is achieved. For most herbicides, selectivity between crops and weeds is the
result of differential abilities to metabolize the herbicide to nonactive products. Crops are able to more effectively and efficiently metabolize the herbicide than the weeds. Differential metabolism of herbicides is influenced by a number of factors including application timing relative to crop and weed stage of development and the overall growth conditions of the plants. The insertion of transgenes, or selection for critical plant enzymes through traditional breeding programs, greatly elevates the differential response of the HR crop and weeds. The mechanism by which the HR crop is protected from the herbicide is either by an alteration of the target enzyme (i.e., glyphosate resistance in soybean) or by the addition of genetic code that allows the crop plant to metabolize the herbicide (i.e., glufosinate in maize).

As the utilization of HR crops does nothing to change the emphasis on herbicides for weed control, public concerns for the negative impacts of herbicides on health and the environment cannot be discounted. Furthermore, whereas the use of herbicides and HR crops are described to be generally beneficial to the environment, provide lower cost of weed management, and allow the farmer to use simpler weed management tactics, there are consequences from using HR crops and herbicides on weed management and weed populations.

These consequences include weed population shifts that favor weed species not effectively managed by the target herbicide, the evolution of biotypes resistant to the target herbicide, the hybridization of the HR crops with closely related weed species and the potential to confer resistance to the resultant progeny, the likelihood that volunteer crops will become HR weeds in rotational crops, and the potential for the HR crops to contaminate non-HR and organically produced crops because of the inability to segregate grain or via pollen movement. In addition, given that multiple applications of the target herbicides are typically required to provide acceptable weed control, there is a greater opportunity for off-target movement of the herbicide. Generally, the adoption of HR crops and subsequent weed control has been a major commercial success. The ability to use registered herbicides that previously did not provide sufficient selectivity between crops and weeds provides an excellent potential to improve the profitability of agriculture and increase weed management options for farmers. Furthermore, many crops do not represent a large enough market opportunity for the agrochemical industry either because of the limited hectares grown or an unacceptable risk of crop injury relative to the profit potential from selling an existing herbicide. Thus weed control options are limited in these crops. Developing HR varieties of these crops will improve weed management options and thus increase yields, grain quality, and profitability. This is an important opportunity to growers who farm smaller areas to achieve more efficient and less expensive weed management.

**IMPACT OF HERBICIDE-RESISTANT CROPS ON CROP PRODUCTION AND ECONOMICS**

The adoption of HR crops has largely been driven by the perceived production benefits ascribed to the HR trait. In Western Canada, an estimated 76% of the hectares seeded to canola are HR varieties. However, most of the HR crop adoption reflects the unprecedented acceptance of HR soybean. An estimated 33.3 million ha of HR soybeans were seeded in 2001 and represented 63% of the GM crops grown worldwide. Herbicide-resistant maize, canola, cotton, and soybean accounted 77% of the hectares planted to GM crops in 2001. The total area planted to HR crops in 2001 was 40.6 million ha. Other HR crops that are approved for production include carnation, chicory, linseed, and tobacco. As many as 14 other crops have transgenic HR cultivars currently under development worldwide.

In total, HR crops represent a major change in crop production tactics and have required major efforts by regulative groups in the federal government to insure that food safety has not changed because of the inclusion of transgenes. From a regulatory perspective, HR and non-HR crops are identical. Importantly, the Environmental Protection Agency has determined that the major HR transgenes are safe, and food developed from HR crops was determined to be no different than food derived from non-HR crops. Canadian regulatory authorities determined that the glyphosate-resistant canola was the same as other cultivars after conducting an extensive series of compositional, processing, and feeding studies. There can be, however, pleiotropic consequences to the addition of the transgene in HR crops.

The economic impact of HR crops on the global agricultural economy is debatable. Farmers and manufacturers of the HR crops report that there are clear and consistent savings in weed management costs compared with weed management not based on HR technology. However, economic analysis suggests that only the manufacturers gained from the HR technology, and farmers received no additional return on their investment when compared with non-HR crops. Furthermore, HR crops may actually incur greater production costs if acceptable tolerances for contamination/segregation (pollen and grain) are not established. The movement of the HR pollen into non-HR crops can result in contam-
inisation of the grain. In addition, the grain-handling industry is not currently able to segregate HR grain from non-HR grain, further increasing the risk of contamination and subsequent economic penalty to the producers.

CONCLUSION

There can be no question that the development of HR technologies has been one of the most important and contentious changes in agriculture. Whereas the adoption of HR technology by farmers has been unprecedented worldwide, acceptance of the technology by consumers is less clear. In fact, the issues about the benefits and risks of HR crops are similar to those voiced by consumers about the adoption of pesticide technologies.[24] On the other hand, the introduction of HR traits by transgene technology could not be readily accomplished by traditional crop breeding tactics, with the exception of resistance to imidazolinone herbicides in several crops. Regardless, the resultant HR traits are portrayed as environmentally and economically beneficial;[25] reports also suggest that the HR crops may have inherent economic risks for growers.[4,21–23] A major component of the debate is that the HR trait is based on herbicidal weed management. The historic baggage of the herbicide use debate has not placed the HR crops in a positive position with the consumers. However, it is clear that farmers have decided that HR crops represent an important benefit to agriculture.

It is interesting to note that the technology that allowed the development of HR crops is predicted to provide new weed management tools not based on herbicides. Three novel approaches to utilizing transgene technology in weed management were reported by Gressel.[26] These were the alteration of biocontrol agents to improve their effectiveness, the use of transgenes to develop more competitive crop either by improving the growth habit or allowing the production of natural allelochemicals, or the alteration of cover crops to make them more applicable in weed management. Thus, whereas it is unclear what the future impact of HR crops will be on world food production, it is clear that transgene technology will play an important role.

Herbicide-Resistant Weeds

Carol Mallory-Smith
Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

The introduction of synthetic herbicides revolutionized weed control. However, the repeated use of herbicides led to the selection of herbicide-resistant weeds. The selection of resistant weeds reduces control options and may increase control costs. In many cases, the most effective and economical herbicide is lost because of resistance. Herbicide-resistant weeds are one of the major challenges in weed management. Although resistance presents a challenge, herbicide-resistant weeds can be controlled with herbicides with different sites of action or other methods of weed control.

BACKGROUND INFORMATION

Herbicide resistance is the inherited ability of a biotype to survive and reproduce following exposure to a dose of a herbicide that is normally lethal to the wild type. Herbicide resistance is an evolved response to selection pressure by a herbicide.

Herbicide-resistant biotypes may be present in a weed population in very small numbers. The repeated use of one herbicide or herbicides with the same site of action allows these resistant plants to survive and reproduce. The number of resistant plants increases until the herbicide is no longer effective. There is no evidence that the herbicide causes the mutations that lead to resistance.

Cross-resistance is the expression of one mechanism that provides plants with the ability to withstand herbicides from different chemical classes. For example, a single point mutation in the enzyme acetolactate synthase (ALS) may provide resistance to five different chemical classes including the widely used sulfonylurea and imidazolinone herbicides. However, cross-resistance at the whole-plant level is difficult to predict because a different point mutation in the ALS enzyme may provide resistance to one chemical class and not others. Cross-resistance also can result from increased metabolic activity that leads to detoxification of herbicides from different chemical classes.

Multiple-resistance is the expression of more than one mechanism that provides plants with the ability to withstand herbicides from different chemical classes. Weed populations may have simultaneous resistance to many herbicides. For example, a common waterhemp (Amaranthus rudis) population in Illinois is resistant to triazine and ALS-inhibiting herbicide classes. However, resistance to these two different classes of herbicides is endowed by two different mechanisms within the same plant. The weed species has two target site mutations, one for each herbicide class. An annual ryegrass (Lolium rigidum Gaud.) population in Australia is resistant to at least nine different herbicide classes. In this case, herbicide options may become very limited. As with cross-resistance, multiple-resistance is difficult to predict; therefore, management of weeds with these types of resistance is complicated.

HISTORY OF HERBICIDE RESISTANCE

It was not long after the commercial use of herbicides that Able and Harper discussed the potential for weeds to evolve resistance. However, the first well-documented example for the selection of a herbicide-resistant weed was triazine-resistant common groundsel (Senecio vulgaris L.), which was identified in 1968 in Washington State. The resistant biotype was found in a nursery that had been treated once or twice annually for 10 years with triazine herbicides. There were earlier reports of differential responses within weed species, but these variable responses to herbicides were not necessarily attributed to resistance.

To date, 281 herbicide-resistant biotypes from 168 species have been identified. The reason that the biotype number and the species number are different is that the same species has been identified with resistance to different herbicides in different locations. Of the 168 species, 100 are dicots and 68 monocots. Resistance has occurred to most herbicide chemical families.

MECHANISMS RESPONSIBLE FOR RESISTANCE

Several mechanisms theoretically could be responsible for herbicide resistance. Those mechanisms include reduced herbicide uptake, reduced herbicide translocation,
herbicide sequestration, herbicide target-site mutation, and herbicide detoxification. In the cases where the resistance mechanism has been determined, the mechanism responsible in most instances has been either target-site mutations or detoxification by metabolism. \[10\]

Target-site mutations have been identified in weeds resistant to herbicides that inhibit photosynthesis, microtubule assembly, or amino acid production. Most often there is a point mutation, a single nucleotide change, which results in an amino acid change and is responsible for the resistance. \[10\] The shape of the herbicide binding site is modified and the herbicide can no longer bind.

Metabolism-based resistance does not involve the binding site of the herbicide, but instead the herbicide is broken down by biochemical processes that make it less toxic to the plant. Several groups of enzymes are involved in the process. Enzymes that are thought to be most important in herbicide metabolism are glutathione S-transferases and cytochrome P450 monooxygenases. \[11,12\]

### FACTORS THAT INFLUENCE THE SELECTION OF RESISTANT BIOTYPES

Resistance usually occurs when a herbicide has been used repeatedly, either year after year or multiple times during a year, and the herbicide is highly effective, killing more than 90% of the treated weeds. The more effective a herbicide, the higher the selection pressure for resistance. Therefore, all herbicides do not exert the same selection pressure.

If a herbicide has only one site of action, it is easier to select a resistant biotype because only one mutation is needed. A herbicide that has soil residual activity will provide more selection pressure because the herbicide remains in the environment and any new seedlings will be exposed to the herbicide. If a herbicide has a very short residual, repeated applications during one growing season can have the same effect.

Herbicide factors influence the selection of herbicide-resistant weeds, but agronomic factors can also be important. Many resistant weed species have been selected in monoculture production systems. These systems result in the repeated use of the same herbicide. The increased reliance on herbicides for weed control along with a concurrent decrease in other weed management tactics further increases selection of resistant biotypes. The introduction of herbicide-resistant crops also increased the use of a single herbicide with decreased alternative controls.

Some weed species seem to be more prone to herbicide resistance than others. Some species have increased mutation rates or increased genetic variability. Increased variability is usually found in cross-pollinating species. Selection of resistant biotypes varies depending upon how likely it is for the resistance mutation to be lethal.

Weeds that produce more than one generation per year may be exposed to herbicides with the same site of action more often than those that produce only one generation per year. Because the selection of a resistant biotype is dependent on the number of individuals that are exposed to the herbicide, those weed species that produce more seeds may also produce a resistant individual more quickly.

Breeding systems and inheritance of the trait will influence how fast resistance spreads once it occurs. If the trait is controlled by one recessive gene, the heterozygote and homozygote dominant plants will be susceptible, so only \( \frac{1}{4} \) of the population will survive herbicide treatment. If the trait is dominant, the heterozygote and the homozygote dominant plants will be resistant, and the population will build quickly because \( \frac{3}{4} \) of the plants will survive herbicide treatment. The trait will be readily moved within and between populations if the weed species outcrosses. In a selfing population, the trait will have reduced movement with pollen. Maternal inheritance will prevent herbicide resistance from moving with the pollen. An example of maternal inheritance is triazine resistance. \[13\]

Fitness is the reproductive ability of an individual, and competitive ability is the capacity of a plant to acquire resources. Initially, researchers assumed that herbicide-resistant weed species would have reduced fitness and competitive ability. Indeed, triazine-resistant weed species do have reduced growth and competitive ability. \[14–16\] However, weeds resistant to ALS-inhibiting herbicides have not consistently had reduced fitness or competitive ability. \[17,18\]

Refuges are a common tactic for the management of insect and pathogen resistance. Susceptible populations are maintained in surrounding areas and can be used to swamp resistance alleles. Generally, pollen and seed are not sufficiently mobile to swamp resistant weed populations. Migration is probably more important in the movement of resistance to a susceptible population than vice versa. This is particularly true with the tumbleweeds. Long-distance movement of a herbicide resistance gene out of an area is most likely to occur through seed movement.

### PREVENTION AND MANAGEMENT OF HERBICIDE-RESISTANT WEEDS

Any management strategy that reduces the selection pressure from a herbicide will reduce the selection for a herbicide-resistant weed in the system. Recommendations for the prevention or management of herbicide-resistant weeds are often the same. \[1\] The recommendations from
the herbicide industry and university personnel include many common factors. Common recommendations are to rotate herbicides with different sites of action to reduce selection pressure, to use short-residual herbicides so that selection pressure during a cropping season is reduced, to use multiple weed-control methods in conjunction with herbicides, and to plant certified crop seed so that herbicide-resistant weed seeds are not introduced into a field. Growers need to keep accurate records of herbicides that have been used on a field so that they can adopt a weed management plan that reduces the selection of herbicide-resistant weeds. The integration of these recommendations will reduce selection pressure for herbicide-resistant weeds.

CONCLUSION

Herbicide-resistant weeds will continue to be an issue for weed management as long as herbicides are used for weed control. Herbicide-resistant weeds can be managed, and no herbicides have been removed from the marketplace because of resistance. When growers use multiple weed-management techniques, the selection of herbicide-resistant weeds is reduced. An integrated approach using crop rotation, herbicides with different sites of action, and alternative weed control such as physical and mechanical weed control is useful in both the prevention of herbicide-resistant weeds and the management of herbicide-resistant weeds if they do occur.

Herbicides in the Environment: Fate of
Kim A. Anderson
Jennifer L. Schaeffer
Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

Herbicides are an integral part of our society; they are used by the general public, governments, institutions, foresters, and farmers. The benefits of herbicides need to be delivered without posing unacceptable risk to non-target sites. Therefore, understanding (and predicting) the environmental fate of herbicides is critically important. Environmental fate is determined by the individual fate processes of transformation and transport. Chemical and physical processes are primary determinants of transformation and transport of herbicides applied to soils and plants. Transformation determines what herbicides are degraded to in the environment and how quickly, while transport determines where herbicides move in the environment and how quickly. Jointly, these processes affect how much of a pesticide and its metabolites (degradation products) are present in the environment, where, and for how long. Herbicide fate also varies in response to changes in environmental conditions and application management practices (e.g., spray drift, volatilization), so it is important to understand these variables as well.

Major environmental compartments for herbicides can be considered as surface waters, the subsurface (soil and groundwater), and the atmosphere. Each medium has its own unique characteristics; however, there are many similarities when considering herbicide movement. Herbicides are rarely restricted to only one medium; therefore, chemical exchange among the compartments must be considered.

Wind erosion, volatilization, photo-degradation, run-off, plant uptake, sorption to soil, microbial or chemical degradation and leaching are potential pathways for loss from an application site. Chemical and microbial degradation are critically important factors in the fate of herbicides. Chemical conditions in soil are important secondary determinants of herbicide transport and fate. The importance of interactions between herbicides and solid phases of soils, soil water, and air within and above soil depends on a variety of chemical factors. Adsorption of herbicides from soil water to soil particle is one of the most important chemical determinants that limit mobility in soils. Environmental fate of herbicides depends on the chemical transformations, degradation, and transport in each environmental compartment.

TRANSFORMATION

Transformations determine how long a herbicide will stay in the environment. Molecular interactions of herbicides are based in part on the herbicide’s chemical nature and are predicated on the physical-chemical properties and reactivities of the herbicide. Several generalized exchange processes between compartments are shown in Fig. 1. In order to understand (and therefore predict) environmental fate, the physical-chemical properties of herbicides must be known. Physical-chemical properties such as molecular formula, molecular weight, boiling point, melting point, decomposition point, water solubility, organic solubility, vapor pressure (V_p), Henry’s law constant (K_HI), octanol/water partitioning (K_ow), acidity constant (pKa), and soil sorption (K_d, K_oc) are important in predicting transformations. How some of these chemical-physical properties affect herbicide fate is briefly discussed (Fig. 2). Table 1,[1-4] demonstrates the wide variation of chemical-physical properties of a selected group of herbicides. Water solubility, the solubility of a herbicide in water at a specific temperature, determines the affinity for aqueous media and affects movement between air, soil, and water compartments. Vapor pressure, the pressure of the vapor of a herbicide at equilibrium with its pure condensed phase, measures a herbicide’s tendency to transfer to and from gaseous environmental phases. Vapor pressure is critical for predicting either the equilibrium distribution or the rate of exchange to and from natural waters. Henry’s law constant (K_HI), the air-water distribution ratio for neutral compounds in dilute solutions in pure water, determines how a chemical will distribute between the gas and aqueous phase at equilibrium. Henry’s law constant, therefore, only approximates the air-water partition in natural
waters. Octanol-water partition coefficient (K_{ow}), the partition of organic compounds between water and octanol, is used to estimate the equilibrium partitioning of nonpolar organic compounds between water and organisms. The octanol-water partition coefficient is also proportional to partitioning of organic compounds (herbicides) into soil humus and other naturally occurring organic phases.

In the environment, many herbicides are present in a charged state (not neutral). Charged species have different properties and reactivities as compared to their neutral counterparts. Therefore, the extent to which a compound forms ions in environmental ecosystems is important. The pKa is a measure of the strength of an acid relative to water. Strong organic acids (pKa $\leq 3$) in ambient natural waters (pH 4–9) will be present predominantly as anions. Conversely, very weak acids (pKa $\geq 12$) in ambient natural waters will be present in their associated form (neutral). In an analogous fashion, strong bases (pKa $\geq 11$) will be present as ions.[5] Examples of weak acids are 2,4-D and triclopyr, and examples of weak bases are atrazine, dicamba, and simazine (Table 1).

Sorption of a herbicide is when the herbicide binds to the soil or sediment particles (K_d). Soil sorption is an important process since it can dramatically affect herbicide fate. Figure 2 illustrates the relationship between herbicides sorbed to soil particles versus those dissolved in soil water. Soil sorption is dependent on soil type and influenced heavily by the organic matter content. Typically, soils high in clay and organic matter have a higher sorption capacity. To account for organic matter content, sorption is sometimes normalized for % organic matter, referred to as K_{oc}. K_d, K_f, and V_p describe the potential for exchange of herbicide compounds between soil, water, and air over short distances.

---

**Fig. 1** Illustrated are pathways for loss of herbicide from a herbicide application site. Each pathway (arrow) illustrates a particular loss process occurring at some rate constant (k). The importance of each pathway and magnitude of each rate constant will vary substantially between herbicides and environmental conditions. (View this art in color at www.dekker.com.)

by diffusion. Transport over longer distances involves mass transfer (advection-dispersion).

TRANSPORT

Transport of herbicides from runoff from soil is an important route of entry into surface waters. Herbicide runoff can be classified into two categories: herbicides that are either dissolved or suspended in runoff waters. Dissolved herbicides are characterized by low adsorption and high water solubility, while suspended herbicides are characterized by high soil sorption. Leaching depends strongly on local environmental conditions, such as percolation rates through local soils. Adsorption decreases herbicide leaching mobility by reducing the amount of herbicide available to the percolating soil water. However, herbicide runoff and leaching also are controlled by the amount of herbicide degradation.

DEGRADATION

Herbicide degradation ultimately ends with the formation of simple stable compounds, such as carbon dioxide; however, there are intermediates of varying stability on the way to complete mineralization (e.g., H₂O and CO₂). The rate of degradation of a particular herbicide can vary widely. The chemical nature of the herbicide is important, as discussed previously, but the degradation rate also depends on the availability of other reactants, as well as environmental factors. There are three major degradation pathways for herbicides: photo-degradation, chemical degradation, and microbial degradation.

Photo-degradation is the breakdown of a herbicide by sunlight at the plant, soil, or water surface. Direct photolysis occurs when a herbicide absorbs light (some portion of the solar spectrum), and this leads to dissociation of some kind (e.g., bonds break). Indirect photolysis occurs when a sensitizer molecule is radiatively excited and is sufficiently long-lived to transfer energy, such as an electron, a hydrogen atom, or a proton to another “receptor” molecule. The receptor molecule (herbicide), without directly absorbing radiation, can be activated via the “sensitizer” molecule to undergo dissociation or other kinds of chemical reactions leading to photo-degradation.

Chemical degradation is the breakdown of herbicides by processes not involving living organisms (abiotic). Hydrolysis may be one of the more important mechanisms of degradation for herbicides. Hydrolysis is the reaction of a herbicide where water interacts with the herbicide, replacing a portion of the molecule with OH. The following functional groups and chemical classes are known to be susceptible to hydrolysis: ethers, amides, phenylurea compounds, nitrile, carbamates, thiocarbamates, and triazines. Hydrolysis is influenced by environmental conditions including pH, water hardness, dissolved organic matter, dissolved metals, and temperature. Half life (t₁/₂) is the amount of time it takes the parent compound (herbicide) to decay to half its original concentration. The half life for chemical degradation via the hydrolysis pathway is strongly dependent on environmental conditions. For example, the t₁/₂ for 2,4-D at pH 6 is four years, while the t₁/₂ at pH 9 is 37 hours.[6]

Microbial degradation is the breakdown of compounds (herbicides) by microorganisms. Bacteria and fungi are the primary microorganisms responsible for biotransformations (biotic reactions). Rates of microbial degradation are largely determined by environmental conditions such as temperature, pH, reduction-oxidation conditions, moisture, oxygen, organic matter, and food. Complete biodegradation, mineralization, yields carbon dioxide, water, and minerals.

CONCLUSION

The perfect herbicide would be one that controls weeds as necessary and then quickly breaks down and never moves off-site. The development of new herbicides over the last decade has focused in part on minimizing unacceptable risk to non-target sites. This has resulted in the development of more biologically active herbicides that greatly reduce application rates. Other research developments include minimizing the leaching of herbicides. When herbicides are applied in the environment, many transport and transformation processes are involved in their dissipation. Predicting herbicide environmental fate and behavior is complicated and is determined by the chemical processes for each environmental compartment.

In addition to understanding the fate of herbicides in the environment, emerging research also endeavors to look at the risk to non-target organisms. The risk of herbicides to organisms is relative to the bioavailability of the herbicide. Bioavailability may be approximately inversely proportional to Kₐ. Herbicides with larger Kₐ’s tend to have lower bioavailability. Along with the determination of transport and transformation chemical processes, understanding the complete risk to non-target sites, therefore, should include the determination of the bioavailability of the herbicide.

INTRODUCTION

Herbs and spices include plants whose leaves, stems, flowering tops, fruits, and roots are used—either fresh, dried, or frozen—in seasoning of foods; in the beverage industry; as dietary supplements; in pharmaceutical, perfumery, and cosmetic products; and for numerous other purposes, including dyeing, potpourris, insect deterrents, and aromatherapy. The distinction between culinary herbs and spices is an imprecise one, and recently the most common term used for both groups is "aromatic and medicinal plants." Scientific and regulatory information is systematically presented and published world-wide at a high rate.

CULINARY HERBS

Culinary herbs are usually defined as edible plants, consumed in small quantities and providing flavor and aroma to foods and beverages. They are predominantly grown in temperate and Mediterranean regions, and can be consumed as vegetables or as condiments. Extracts of these plants, in the form of essential oils and oleoresins, are also increasingly employed in various industries.

Herbs have been used traditionally for centuries to add flavor to monotonous diets. Onion, garlic, leek, parsley, sage, celery, mustard, dill, and lovage can serve as examples. Each country and locality, however, offers the local population a collection of potential herbs, shrubs, and woody plants that have been employed in culinary traditions among ethnic groups. Among culinary herbs, 85 genera are described comprehensively by Small, who gives examples of traditional herbs, edible sprouts, and edible flowers. Many herbs can contribute significantly to nutrient food value, specifically for their content of vitamins and minerals, and for their antioxidant and/or anticancer properties. Over 100 species of herbs and spices are used to brew tea, but the safety of some of these is open to question. It is important to be sure about high standards for the labeling, safety, and efficacy of any herb obtained on the market.

There are few true varieties of even the most familiar culinary herbs that would pass the rigorous testing applied to major crops (distinctness, uniformity, and stability). Most named varieties arise from simple selection, and they can display large variation in morphology, physiology, and the chemistry of both primary and secondary metabolites. Many varieties are selected on the basis of their suitability for a particular region, and the behavior of such cultivars in another environment may be quite different. Herbs can be subjected to various treatments such as extraction, distillation, expression, fractionation, purification, concentration, or fermentation. The extraction process has a big influence on the composition of the resulting extract. It is important to control every part of the process in order to obtain reproducible and commercially marketable extracts.

The commercial growing of a herbal crop requires a stable supply of uniform seeds or propagules. The composition and quantity of flavor and fragrance chemicals in plants changes during the growing season; consequently, harvest time is very important. The effects of fertilizers, herbicides, pesticides, and heavy metals have to be considered for each species. Sun radiation, rain, altitude, and day-length also play an important role in the production of these chemicals in plants, and, finally, post-harvest processing and storage can markedly influence the quality of the final product.

MEDICINAL HERBS

Knowledge of medicinal properties of herbs has been handed down from generation to generation for thousands of years. Ancient herbal records from China, India, and Egypt dating back to 3000–1000 B.C. belong to the oldest archaeological finds. Plants mentioned in Western herbals, mainly by Greek physicians (for example, De Materia Medica by Dioscorides, from the 1st century A.D.), followed by herbals from Middle Ages Europe (Gerard, Culpeper), and many new herbals from the 18th and 19th centuries were used continuously until the onset of synthetic medicinal products in the 20th century. These plants are potentially a vast source of new drugs. Thousands of compounds have been isolated and tested for their pharmacological activities: antibacterial, antiviral, antitumor, antiinflammatory, antioxidant, hypo-
glycemic, and antiulcer.\textsuperscript{[5]} Many other biologically active compounds can be identified, with hallucinogenic, cardiovascular, muscle relaxant, and antileukemic properties. Some 80\% of the world’s population still relies on traditional, plant-based medicine, despite major advances in developing synthetic drugs. The World Health Organization has compiled a list of 20,000 medicinal plants in use. Medicinal plants possess therapeutic properties, and many plant species are not just medicinal, but can be used also as herbs or as an edible vegetable. Certain species can be highly poisonous, such as \textit{Hyoscyamus niger} (henbane), \textit{Datura stramonium} (Jimson weed), \textit{Veratrum album} (white hellebore), and \textit{Digitalis lanata}. A large group of herbs is not poisonous, however, and these are widely used for their medicinal properties. Their pharmacological activities depend on plant metabolism products: carbohydrates, lipids, proteins, phenols, coumarins, flavonoids, anthocyanins, tannins, quinones, terpenoids, steroids, and alkaloids.\textsuperscript{[6]} These plant products form starting materials for the synthesis of drugs, food additives, fragrances and flavors, and insecticides and pesticides.

Claims for the effectiveness and safety of herbal remedies are generally based on historical experience, but therapeutic effects have been recently demonstrated in scientific investigations, and this validation process continues. The world-wide herbal products industry is worth an estimated £11 billion per annum, and this is increasing at 5–10\% per annum. The increased demand for herbal medicines and alternative remedies is driven by consumers for a number of reasons, including an aging population, increased recognition of the importance of diet to long-term health, and an increase in the availability of pharmaceuticals and natural remedies. Significant numbers of herbs (70–90\% of 21,000 species used all over the world) are obtained through commercial collection from their natural habitat. The underground parts include the root (\textit{radix}), rhizome (\textit{rhizoma}), tuber (\textit{tuber}), and bulb (\textit{bulbus}); the aerial parts are the leaf (\textit{folium}), herbage (\textit{herba}), flower (\textit{flos}), fruit (\textit{fructus}), seed (\textit{semen}), and bark (\textit{cortex}). There are particular problems in collecting from the wild, including a mistaken identification of the plants leading to poisoning, and the localized extinction of plants leading to reduced biodiversity. At least 150 medicinal and aromatic plant species are threatened as a result of overcollection and destructive harvesting techniques, as well as habitat loss and changes in their area of distribution.

Qualified medical advice should be sought before using the information provided by various books and leaflets. Herbal remedies are very powerful and are not safe simply because they are natural. Standardization is done in order to obtain herbs and their extracts with reproducible therapeutic activity from batch to batch. The herbs and their extracts must not be toxic, must not interact with other medicines that the consumer may be taking, and
must not be contaminated with pesticide residues, heavy metals, or microbes. The main concerns involving yeasts and filamentous fungi are caused by species of *Aspergillus*, *Penicillium*, *Mucor*, *Rhizopus*, *Absidla*, *Alternaria*, *Cladosporium*, and *Trichoderma*. Both fresh and dried herbal material can also support heavy bacterial loads. Imported plant material can be of poor quality due to the use of irrigation water contaminated with sewage sludges. The guidelines for good agricultural practice (GAP) for aromatic and medicinal plants in the European Union are intended to be applied to the growing and primary processing of all these plants used in the food, feed, medicinal, flavoring, cosmetic, and perfume industries.

**SPICES**

Spices are usually of tropical or subtropical origin, highly aromatic, and with a high percentage of volatile oils.[7] Spices from plant sources have been used throughout history for their presumed preservative properties, and for

---

Fig. 2 Field-scale mobile distillation equipment for chamomile harvest. Norfolk, UK, summer 2001. (View this art in color at www.dekker.com.)
perfumery and flavor purposes. The economies of many countries were based on trade in spices, which brought them wealth and power. At present, the bulk of the world spice trade is concentrated in black and white pepper, clove, nutmeg, cardamom, cinnamon, ginger, mace, and allspice. Accurate statistics are difficult to obtain, because the figures for individual species are not recorded separately. The American Spice Trade Association provides up-to-date information on importing, market trends, quality standards, production, and processing.

Spices can be used either whole or ground, single or blended, or in dried or frozen form. They can be further processed, encapsulated, dispersed, solubilized, and sterilized. Detailed specification standards concerning the amount of volatile oils, total ash, fiber, moisture, specific gravity, and other characteristics are increasingly more strict.

ESSENTIAL OILS

Essential oils are isolated from various parts of the plant: leaves (mint, savory, oregano, lavandula), bark and wood (cinnamon, frankincense, juniperus), root (vetiver), rhizome (ginger), flower bud (cloves), seed (nutmeg, caraway, dill), or flowers (jasmine, roses). Over 3000 essential oils have been identified from a vast number of plants belonging to some 87 families. The knowledge of botany, taxonomy, chemotaxonomy, and biochemistry greatly added to the production and utilization of these oils in the food, drink, pharmaceutical, and cosmetics industries.

Accumulation and secretion of volatile oils in plants is generally associated with the presence of glandular structures, either external or internal, such as oil cells, glands, glandular hairs, resin ducts, canals, and laticifers. It is assumed that the volatile oils are produced within the secretory cells of these structures, which are characteristic for each plant species (Fig. 3). Extraction techniques (using olive oil, for example) and basic distillation have been known since pre-Christian times. Considerable improvement and development occurred from the 14th century, when various pharmacies started to prepare plant-based oil remedies. In the first half of the 19th century the production of essential oils was industrialized and was followed by isolation of single organic compounds from the oil (e.g., cinnamaldehyde from cinnamon oil). Later, the first synthetic aroma molecules were synthesized by the chemical industry. At present, thousands of flavor and fragrance molecules have been isolated, and their structures have been elucidated. Consequently, these molecules can be synthesized. Natural products are obtained directly from plant sources. Nature-
identical compounds are produced synthetically, and they are chemically identical to their natural counterparts. Artificial flavor substances have not been yet identified in plant or animal products, but they are produced artificially. Lists of approved flavoring substances (GRAS—generally recognized as safe) are published in the CFR (Code of Federal Regulations of the U.S.A.); by the FEMA (Flavor and Extract Manufacturers Association of the United States); and by EC Regulation No. 2232/96. Hundreds of monographs on fragrance material and essential oils have been published by the Research Institute for Fragrance Materials in Food and Chemical Toxicology.

CONDIMENTS

The word condiment is derived from the Latin condimentum, which means seasoning, and from condire, which means to pickle. Salt, pepper, mustard, various sauces derived from fruit, vegetables, herbs and spices (soya, horseradish, wasabi, mooli, onion, garlic, chilli, mint, cranberry, dill, watercress, curry, basil), chutneys, relishes, and preserves belong to this group. Practically any type of herb or spice can be used for flavor, preserves, spiced sauces, and drinks.

Heterosis: Effects of Long-Term Selection

O. S. Smith
Pioneer Hi-Bred International, Johnston, Iowa, U.S.A.

INTRODUCTION

Hybrid vigor or heterosis in plant hybrids was first studied by Koelreuter in 1763. The commercial utility of heterosis traces back to the studies of the effects of cross- and self-fertilization in maize, done by E. M. East and G. H. Shull in the early 1900s. This work led to the development of hybrid maize, which by the 1940s had replaced open pollinated varieties of maize in the United States. Almost immediately after the discovery of the commercial utility of heterosis, studies were undertaken to understand the genetic basis of heterosis. For many years these studies attempted to determine the underlying cause of heterosis focusing on the dominance hypothesis vs. the overdominance hypothesis. Numerous scientific conferences have been held on heterosis starting with the Heterosis Conference held in Ames, Iowa, in 1950, where a relatively young scientist by the name of James Crow gave a presentation on “Dominance and Overdominance” and concluded that based on the then available information overdominance was likely a major contributor to heterosis in maize. G. F. Sprague also gave a presentation at this conference entitled “Early Testing and Recurrent Selection,” detailing the results of recurrent selection studies (started in the early 1940s) as a method of developing improved source populations. Two long-term recurrent selection programs in maize that were initiated in the 1950s, as well as other shorter term programs, have allowed the examination of the effects of long-term selection on heterosis in species of agronomic importance. In addition, several long-term selection studies have been conducted in model species, i.e., Drosophila sp. and Tribolium to look at the effects of recurrent selection on heterosis.

HETEROSIS AND RECURRENT SELECTION

East and Hayes at the turn of the century demonstrated the importance of heterosis in maize.[1] Crow[2] argued that the large amount of heterosis in maize was likely due to overdominant gene action (but see Ref.[3]) and Sprague[4] demonstrated the effects of recurrent selection in the parental populations on the performance of the population cross. Falconer[5] and Wilhelm and Pollack[6] developed single locus heterosis theory, which demonstrated that the heterosis in an F1 cross, whether the F1 is a cross between two inbred parents or a cross between two random mating populations, is a function of the difference in allele frequencies in the parents and the degree of directional dominance. More recent work[6] has shown that both additive-by-additive and dominance-by-dominance types of epistasis for loci showing differences in allelic frequencies also contribute to the observed heterosis.

Reciprocal recurrent selection (RRS)[7] was proposed as a breeding method that would utilize all types of gene action in simultaneous improvement of two populations where the goal was to develop hybrids. After RRS was proposed several long-term selection programs, involving several species, were initiated to examine the efficiency of RRS and to look at the performance of the improved population hybrids.[8–11] In general, the population crosses showed a linear response to selection with little or no gains in the populations per se. Therefore, there is an increase in heterosis in the population cross for these populations undergoing selection. The increase in performance of the population cross for the maize populations involved in RRS does not appear to be specific to the populations involved in the RRS programs. In two of these programs the population cross between populations undergoing intrapopulation improvement, Jarvis(FS) and Indian Chief(FS), showed nearly identical response to selection in crosses with each other, and with the version of these populations undergoing RRS. This rate of improvement was comparable to the rate of improvement in the population cross developed from the versions of these populations undergoing RRS. This was also true for the BSSS(R) and BSSS(HT) (RRS and half sib selection with a double cross tester) populations when crossed to BSCB1(R), the reciprocal population in the Iowa State RRS program. The change in heterosis for the population cross was not quite as great as for the populations undergoing interpopulation improvement as for populations undergoing intrapopulation improvement. The improvement in the populations per se was greater for the interpopulation vs. intrapopulation improvement programs. For both selection schemes, the expectation is that favorable alleles for genes with additive and or partial dominance effects will move to fixation for the favorable allele. However, for loci showing complete dominance,
as soon as the favorable allele becomes fixed in one of the populations undergoing RRS, the selection differential goes to zero \[12\] and the allele in the second population changes randomly due to drift and may even be lost from the population, depending on the allele frequency at the time the favorable allele is fixed in the other population. For loci showing overdominance or pseudo-overdominance, the expectation is for different alleles to be fixed in the two populations undergoing RRS but stay at intermediate frequencies in the populations undergoing intrapopulation improvement. Smith \[13,14\] and Hanson \[15\] proposed two different methods to look at the changes in heterosis in long-term selection populations. The method by Smith is based on linear functions of population and population cross means to estimate changes in allele frequencies of alleles with additive and dominance effects, changes in heterosis effects, as a function of differences in allele frequency changes in the two populations undergoing selection, and effects due to drift resulting from finite population sizes. This analysis is based on a genetic model that includes simple additive and dominance effects, and multiple alleles. Individual loci effects are then summed over loci and no epistatic effects are included. This analysis has been used to analyze several populations undergoing long-term selection and has shown that the increases in heterosis in the long-term selection populations can be attributed to the effects of drift, whereas significant changes in the amount of heterosis due to selection have not been observed. The analysis proposed by Hanson is based on using diallel crosses to estimate the divergence of the populations undergoing selection as a function of changes in allele frequencies of alleles showing nonadditive effects, i.e., dominance and epistasis. This analysis has demonstrated that the genetic distance between these long-term populations has increased and that there has been an increase in heterosis in the population cross. However, the analysis does not determine if the changes in allele frequencies are a function of drift or selection. The changes in allele frequencies have been examined in the long-term RRS program involving the Iowa Stiff Stalk BSSS(R) and BSCB1(R) populations with the use of molecular markers \[16\]. The analysis indicated that these two populations are moving toward fixation of different alleles in the two populations. Some of the allele frequency changes appear to be due to selection, whereas drift effects could not be ruled out as contributing to changes in allele frequencies at the majority of the loci that showed allele frequency changes.

The results of these and other studies in model species demonstrate that recurrent selection is effective in increasing the heterosis in population crosses of these populations. However, because so little is still known about the genetics of heterosis, and due to the effects of finite population size on allele frequency changes, it is not known precisely what the effects of the long-term selection on the phenomenon of heterosis are. These long-term selection populations should be extremely valuable resources as new molecular tools are applied to provide a better understanding of the genetics and of the molecular basis of heterosis. Recent studies have pointed to two areas that may be important to the understanding of heterosis, allele specific expression \[17\] and the lack of microsynteny \[18,19\].

Human Cholinesterases from Plants for Detoxification

Tsafrir S. Mor
Arizona State University, Tempe, Arizona, U.S.A.

Hermona Soreq
The Hebrew University of Jerusalem, Jerusalem, Israel

INTRODUCTION

Acetylcholinesterase (AChE) is a major component of central and peripheral neurotransmission, terminating signals at cholinergic synapses by hydrolyzing the neurotransmitter acetylcholine. During the past decade, nonenzymatic roles for AChE and the homologous enzyme butyrylcholinesterase (BChE) were recognized. Cholinesterases in the bloodstream may play a protective role by metabolic inactivation of many nerve agents, including natural and synthetic anticholinesterases (e.g., organophosphate nerve gases and pesticides), street drugs (e.g., cocaine and heroin), and muscle relaxants (e.g., succinylcholine). The use of exogenously applied cholinesterase in treatment and prevention of intoxication by these toxicants is being evaluated. For therapy based on cholinesterases to be feasible, large amounts of properly folded and stable enzymatic preparations that are free of mammalian pathogens are needed. Transgenic plants are emerging as one of the more promising alternative production systems for pharmaceutically important proteins; however, very little is known about the rules controlling posttranslational processing of such proteins, including protein folding, glycosylation, etc. Human AChE in tomato plants has recently been expressed; this system is being evaluated as an expression system for other variants of cholinesterases. Beyond the importance of these cholinesterases as scavengers of a wide scope of toxicants, these enzymes are an excellent model for studying posttranslational modifications of recombinant proteins produced in plants.

HUMAN CHOLINESTERASES

Cholinesterases (ChEs) can be distinguished by their substrate and inhibitor-binding specificities.\(^1\) The hydrolytic activity of acetylcholinesterase (AChE) is limited to the neurotransmitter acetylcholine (ACh) which selectively interacts with a narrow group of inhibitors.\(^1\) Mammals possess a homologous serum enzyme—butyrylcholinesterase (BChE)—that has a broader catalytic spectrum with preference for longer-chain substrates\(^3\) and noncholine substrates such as cocaine.\(^4,5\)

In humans, AChE and BChE are encoded by single genes, with the primary transcript of the ACHE gene subjected to alternative splicing, yielding three mRNA variants resulting in three protein isoforms with distinct C-termini with clearly defined spatiotemporal expression patterns, subunit structures, subcellular localization, and subtly different enzymatic properties. (Fig. 1).\(^6\) The catalytic core of human AChE, common to all variants, is sufficient for ACh hydrolysis. Posttranslational modifications of ChEs include glycosylation oligomerization and membrane anchoring via protein-protein interactions (AChE-S) or a glycolipid (AChE-E).\(^7\)

Exposure to anti-AChE agents leads to overstimulation of cholinergic pathways and potentially death.\(^2\) Whereas some naturally occurring AChE inhibitors are very potent, clinically relevant human exposure to them is rare. However, synthetic anti-AChE compounds—especially organophosphates (OPs)—are widely used as pesticides and pose a substantial occupational and environmental risk. Even more ominous is the fear of deliberate use of OPs as chemical warfare agents. Current medical intervention in the case of acute exposure to anticholinesterase agents includes use of the muscarinic ACh-receptor antagonist, atropine, and oximes to reanimate the OP-modified AChE. The reversible carbamate pyridostigmine bromide is also used for prophylaxis.\(^2\) However, these conventional treatments have limited effectiveness and may have serious short- and long-term side effects, including significant performance deficits and even permanent brain damage.

A different approach in treatment and prevention of anti-AChE toxicity seeks to mimic one of the physiological lines of defense. In humans, ChEs can be found in the bloodstream, either in the serum (BChE and AChE-R) or anchored to erythrocytes (AChE-E). Evidence suggests that these enzymes act as scavengers of potentially harmful substances, preventing them from accumulating and reaching their targets. For example, these circulating ChEs can bind and inactivate anticholinesterases, thereby protecting AChE-S, the vital synaptic isoform of AChE.
Administration of exogenous ChEs to boost the potential of the native circulating enzymes to scavenge anticholinergic agents is an efficacious and safe approach for the treatment of anti-AChE toxicity. The efficacy of this therapeutic paradigm to protect against a challenge of organophosphates was proven in a variety of animal models.[8,9] Similarly, administered BChE is effective in the metabolic inactivation of cocaine (in case of overdose) and muscle relaxants (e.g., to treat succinylcholine postanesthesia apnea that occurs in patients with genetic or acquired low-plasma BChE activities).[4,5]

HUMAN AChE PRODUCTION IN PLANTS

To be used as detoxifiers, ChEs can be purified from human or animal blood, but these sources are supply-limited and have inherent problems (e.g., potential contamination with human pathogens and prions). Various cell cultures have been explored as systems for the production of recombinant ChEs but suffer from disadvantages. Recombinant ChEs expressed in *Escherichia coli* must be denatured and renatured, and even then have only partial activity. In addition, they are extremely labile as compared to the native enzymes.[10] Production of ChEs by yeast cultures[10] or in insect cells by the baculovirus vector system[11] is possible but remained small scale, perhaps reflecting yield problems. Production in mammalian cell cultures is possible and was extensively studied;[12] however, the costs of production (and scaling up) as well as the safety of this system are major shortcomings.

We recently introduced transgenic plants as a novel production system for human AChE, when we successfully expressed the catalytic domain of the enzyme (common to all variants) in tomato plants and reported on the initial characterization of this recombinant protein (Fig. 2).[13] This was the first demonstration of expression in plants of a key protein component of the human nervous system. Some of the transgenic tomato lines express high levels of AChE activity, comparable to those reported for production of the enzyme in yeast. The activity is typical of authentic human AChE activity as judged by its substrate and inhibitor interactions. The plant-derived enzyme is relatively stable in the crude plant extract.[13] More recently, we introduced the same construct to *Arabidopsis thaliana* and demonstrated the presence of AChE in such putative transformants by activity assays. Indeed, the AChE activities measured in leaf extracts of these plants were higher than previously seen in our best-expressing tomato lines (Fig. 2), probably reflecting the presence of a naturally occurring ChE inhibitor in the tomato extracts (Mor et al., manuscript submitted).
CONCLUSION

Anticipating a growing need for large amounts of ChE that will be properly folded, stable, enzymatically active, and free of mammalian pathogens, we advocate transgenic plants as a suitable system for production of these human enzymes. Our previous results demonstrate that as an expression system for ChEs, the potential of transgenic plants is still far from being fully realized. To make this prospect a reality the system must be optimized to maximize expression of the recombinant protein. For example, we have redesigned the coding regions of the DNA constructs encoding the various AChE isoforms to conform their codon usage to that which prevails in plants and to eliminate deleterious sequences that might hamper their expression in plants. As this encyclopedia goes to print, we are analyzing transgenic plants that harbor these plant-optimized synthetic genes, that show a dramatic increase in their expression levels. We are also exploring various options for targeting the transgenic enzyme to subcellular compartments that would allow maximal accumulation of the recombinant proteins, and for screening for the best host plant species for the purpose. Further challenges include establishing a purification scheme for the recombinant plant-produced AChE (made easier with increased expression levels) and subsequent testing of the enzyme’s ability to protect animals from OP intoxication.

In more general terms, whereas the basic requirements for expressing mammalian proteins in plants are quite well established, little is known of the rules controlling the posttranslational processing events (including protein folding, glycosylation, etc.) that such recombinant proteins undergo in plant cells. ChEs are appropriate models for studying these topics because in mammals they exist as different, well-studied variants with distinct posttranslational modifications that give them their unique biochemical properties. By biochemical characterization of the plant-produced ChEs and comparison to their native counterparts, important insights can be gained to establish the universal utility of plants for the production of pharmaceutically valuable proteins.

Hypersensitive Response in Plants

Ron Mittler
University of Nevada, Reno, Nevada, U.S.A.

INTRODUCTION

The hypersensitive response is a programmed cell death process activated in many plants in response to pathogen attack. It inhibits the rate of pathogen spread during infection and, in coordination with other defense mechanisms, such as pathogenesis-related proteins and phytoalexins, serves to protect plants from infection by different obligatory pathogens, including viruses, bacteria, and fungi.

BACKGROUND

The hypersensitive response (HR) is a rapid cell death process activated in many plants in response to pathogen attack. During this response, the plant sacrifices some of its cells to circle the invading pathogen with a layer or a ring of dead cells (Fig. 1). It is believed that this response serves to inhibit the growth of the invading pathogen by killing of infected and noninfected cells and producing a physical barrier composed of dead plant cells. The rapid dehydration that follows the death of plant tissue may also have deleterious effects on pathogen growth by limiting the availability of nutrients. During the HR, dying plant cells strengthen their cell walls by deposition of different phenolic compounds, synthesize different toxic compounds called phytoalexins, and accumulate many proteins with antimicrobial activity called pathogenesis-related proteins. Activation of the HR results in the formation of a distinct lesion on leaves or stems, termed a HR lesion (Fig. 1), and the pathogen is generally restricted to this lesion. Many plant pathogens that invade and successfully colonize plants lead eventually to the formation of disease symptoms in the form of lesions or patches of dead cells. However, these mostly develop within hours, while HR lesions develop within hours, hence the term “hypersensitive response.”

Different pathogens such as bacteria, fungi, and viruses induce different types of HR cell death with different morphological and physiological characteristics. Nevertheless, it appears as if the sacrifice of cells by the plant to inhibit pathogen growth and prevent systemic infection is the main function of the HR. This function may be similar to the activation of apoptosis or programmed cell death (PCD) in response to infection with viruses or bacteria in animal cells. Thus activation of cell death as a means of preventing further infection by an invading pathogen appears to be a general theme in the biology of multicellular organisms.

The HR can be very successful in preventing obligate parasites, which absolutely require living cells, from replicating within plant tissues. However, it was recently shown that some pathogens that feed on dead plant tissue (necrotrophic pathogens) deliberately activate the HR of some plants to propagate on the resulting dead plant tissue.

Genes and Pathways of the Hypersensitive Response

Major players involved in the activation of the HR are reactive oxygen intermediates (ROI), nitric oxide (NO), calcium and proton pumps, mitogen-activated protein kinases (MAPKs), and salicylic acid (SA). It is believed that the initial recognition of the pathogen via a plant-pathogen receptor (part of the gene-for-gene response) activates a signal transduction pathway that involves the translocation of calcium and protons across the plasma membrane into the cytosol, protein phosphorylation/dephosphorylation events, the activation of enzymes that generate ROI such as NADPH-oxidase and peroxidases, and the accumulation of NO and SA. Manipulations of proton and calcium homeostasis were shown to activate the HR. These include pharmacological studies and the expression in plants of a proton channel that localized to the plasma membrane and activated the HR. A combination of enhanced production of ROI and NO was also shown to activate the HR in the absence of a pathogen, and SA was shown to facilitate the formation of ROI as well as to inhibit catalase and ascorbate peroxidase, two of the key ROI removal enzymes in plants. These processes are thought to be orchestrated by a cascade of MAPKs.

Several lines of evidence suggest that the HR results from the activation of a PCD process. These include the activation of cell death in the absence of pathogens by mutations in certain genes thought to be involved in the cell death pathway, the activation of cell death upon
recognition of elicitors which are compounds produced by the pathogen, and the activation of the HR by expression of different foreign genes in plants. That cell death resembling the HR can be activated in the absence of a pathogen strongly suggests that this type of cell death is not directly caused by the invading pathogen but rather results from the activation of a host-encoded pathway for PCD. Moreover, activation of cell death during the HR was shown to require the activity of the plant transcription and translation machinery.[11] These findings further suggest that genes encoded by the plant are actively involved in the death of plant cells during the HR.

Perhaps the most compelling evidence that the HR is a PCD process is the existence of mutants that spontaneously activate the HR in the absence of a pathogen.[12] These mutants are often referred to as “disease lesion mimics.” Two additional terms used to describe these mutants are “accelerated cell death” and “lesion-simulating disease.” The mutations that cause the appearance of HR lesions in the absence of a pathogen are thought to occur in plant genes that control PCD. Thus mutations in these genes would result in the abnormal activation or suppression of pathogen-induced PCD. Disease lesion mimic mutants have been isolated from tomato, maize, barley, rice, and Arabidopsis. They were classified according to their appearance into two groups: initiation and feedback or propagation mutants.[12] This classification is based on the assumption that two mechanisms are involved in coordinating the HR: a pathway for the initiation of PCD and a pathway for the inhibition of cell death.

Cell death mutants are powerful tools for the study of PCD in plants. By crossing of these mutants for complementation studies, the order of the cell death genes along the PCD pathway may be determined.[13,14] For example, it was recently reported that LSD1, a novel zinc finger protein that regulates PCD induced by superoxide or pathogen infection, down-regulates a PCD pathway that is driven by ROI, SA, and the plant genes PAD4, EDS1, and NPR1. This pathway is activated in cells that surround the initial infection site. Thus when LSD1 is mutated, it can no longer suppress PCD in these cells, and the lesion that is formed upon infection or superoxide application becomes a runaway cell death process that spreads to the entire leaf instead of being confined to only a few cells.

**Programmed Cell Death Genes in the Hypersensitive Response**

The sequencing of the entire genome of the flowering plant Arabidopsis thaliana failed to identify plant homologs of key regulators of PCD in animals such as caspases, Bcl-2, or Bax. Plants were, however, found to contain a group of proteases called metacaspases, homologs of Bax inhibitor-1 (BI-1), and Defender Against Death-1 (DAD-1).[15] Molecular and pharmacological studies support the involvement of caspases in the HR (possibly mediated by the metacaspase family). These include the suppression of HR by synthetic peptides that act as inhibitors of caspase activity and measurements of caspase-like protease activity in plant cells undergoing HR-PCD.[15] Thus in plants, metacaspases may play a similar role to caspases in animals. Additional players that may be similar to some of those controlling PCD in animals are small GTP-binding proteins of the Ras class and cystein-sensitive proteases.

Although Bax homologs were not found in plant cells, expression of Bax in plants induces PCD.[16] Moreover, this induction requires the proper oligomerization and cellular localization of Bax in plants. The animal protein BI-1 was recently found to inhibit Bax toxicity in yeast. Homologs of this protein were found in plants. Co-expression of Bax and the plant homolog of BI-1 resulted in the inhibition of Bax-induced cell death in plants.[16] These results as well as the finding that mitochondrial permeability transition and release of cytochrome c from mitochondria accompany certain types of PCD in plants suggest an active role for the mitochondria in plant HR-PCD processes. Further support for this hypothesis comes from overexpression of animal anti-apoptotic genes such as Bcl-2, Bcl-XL, and Cell Death-9 (CED-9) in plants. These were found to inhibit pathogen-induced PCD and oxidative stress-induced PCD in plants.[17,18] A recent homology search using BI-1 sequences revealed the possible existence of a functional homolog of Bcl-2 in plants (called ABR proteins; Ref. [15]). However, further experimental work is required to support this possibility.

**Fig. 1** A photograph of a HR lesion, resulting from the infection of a tobacco leaf with tobacco mosaic virus. The diameter of the lesion shown in the photograph is about 0.75 mm.

---

**2 Hypersensitive Response in Plants**

Barley, rice, and Arabidopsis mimic mutants have been isolated from tomato, maize, suppression of pathogen-induced PCD. Disease lesion of HR lesions in the absence of a pathogen are thought toulating disease.’’ The mutations that cause the appearance mutants are ‘‘accelerated cell death’’ and ‘‘lesion-simulating disease.’’ The mutations that cause the appearance of HR lesions in the absence of a pathogen are thought to occur in plant genes that control PCD. Thus mutations in these genes would result in the abnormal activation or suppression of pathogen-induced PCD. Disease lesion mimic mutants have been isolated from tomato, maize, barley, rice, and Arabidopsis. They were classified according to their appearance into two groups: initiation and feedback or propagation mutants. This classification is based on the assumption that two mechanisms are involved in coordinating the HR: a pathway for the initiation of PCD and a pathway for the inhibition of cell death.

Cell death mutants are powerful tools for the study of PCD in plants. By crossing of these mutants for complementation studies, the order of the cell death genes along the PCD pathway may be determined. For example, it was recently reported that LSD1, a novel zinc finger protein that regulates PCD induced by superoxide or pathogen infection, down-regulates a PCD pathway that is driven by ROI, SA, and the plant genes PAD4, EDS1, and NPR1. This pathway is activated in cells that surround the initial infection site. Thus when LSD1 is mutated, it can no longer suppress PCD in these cells, and the lesion that is formed upon infection or superoxide application becomes a runaway cell death process that spreads to the entire leaf instead of being confined to only a few cells.

**Programmed Cell Death Genes in the Hypersensitive Response**

The sequencing of the entire genome of the flowering plant Arabidopsis thaliana failed to identify plant homologs of key regulators of PCD in animals such as caspases, Bcl-2, or Bax. Plants were, however, found to contain a group of proteases called metacaspases, homologs of Bax inhibitor-1 (BI-1), and Defender Against Death-1 (DAD-1). Molecular and pharmacological studies support the involvement of caspases in the HR (possibly mediated by the metacaspase family). These include the suppression of HR by synthetic peptides that act as inhibitors of caspase activity and measurements of caspase-like protease activity in plant cells undergoing HR-PCD. Thus in plants, metacaspases may play a similar role to caspases in animals. Additional players that may be similar to some of those controlling PCD in animals are small GTP-binding proteins of the Ras class and cystein-sensitive proteases.

Although Bax homologs were not found in plant cells, expression of Bax in plants induces PCD. Moreover, this induction requires the proper oligomerization and cellular localization of Bax in plants. The animal protein BI-1 was recently found to inhibit Bax toxicity in yeast. Homologs of this protein were found in plants. Co-expression of Bax and the plant homolog of BI-1 resulted in the inhibition of Bax-induced cell death in plants. These results as well as the finding that mitochondrial permeability transition and release of cytochrome c from mitochondria accompany certain types of PCD in plants suggest an active role for the mitochondria in plant HR-PCD processes. Further support for this hypothesis comes from overexpression of animal anti-apoptotic genes such as Bcl-2, Bcl-XL, and Cell Death-9 (CED-9) in plants. These were found to inhibit pathogen-induced PCD and oxidative stress-induced PCD in plants. A recent homology search using BI-1 sequences revealed the possible existence of a functional homolog of Bcl-2 in plants (called ABR proteins; Ref. [15]). However, further experimental work is required to support this possibility.
CONCLUSION

The hypersensitive response is a programmed cell death process activated in different plant tissues in response to pathogen attack. It inhibits the rate of pathogen spread during infection, and in coordination with other defense mechanisms, such as pathogenesis-related proteins and phytoalexins, it serves to protect plants from infection by different obligatory pathogens, including viruses, bacteria, and fungi.

In Situ Conservation for Genetic Diversity: Reserve Designation and Design

Ayfer Tan
Ahmet Semsettin Tan
Aegean Agricultural Research Institute, Menemen, Izmir, Turkey

INTRODUCTION

In this article we will briefly define the basic terms of designation and design of genetic reserves for the in situ conservation of the genetic diversity of wild crops and plant species. Readers are encouraged to refer to the citations and “Articles of Further Interest” for more information.

EMERGENCE OF IN SITU CONSERVATION

Many species, which are the component of natural resources, are declining to critical population levels. Important habitats are being destroyed, fragmented, and degraded, and ecosystems are being destroyed through climate change, pollution, invasive species, and direct human impacts such as overexploitation. The International Union for Conservation Nature (IUCN) has been developing a system for describing the conservation status of species since 1963. About 5700 plants were assessed as threatened in 2002[1] and in need of protection by the various means of conservation strategy in banks and/or in natural habitats.

Following considerable public awareness about nature conservation, national and international in situ biodiversity conservation programs have increased. The Convention on Biological Diversity (CBD) promotes in situ conservation and calls on signatory nations to conserve the biological diversity with the aim of insuring the conservation of ecosystems and agrobiodiversity for sustainable utilization of natural resources.

In situ conservation can be defined as “the maintenance of viable diverse population of species in their original surroundings or in their ecosystem and natural habitat.”[2] No species is static but is continually interacting with the physical environment and is competing with the other species in the ecosystem. Consequently, in situ conservation is more dynamic in nature and allows the continuity of evolution.

Crops still depend upon the broad genetic base that exists in their wild relatives. This base is used as a source for crop improvement by means of conventional interspecific hybridization methods and modern genetic manipulation techniques. There is tremendous success with ex situ conservation of wild species, but in situ conservation has been inadequately applied. In situ implementation requires appropriate strategies to overcome socioeconomic and political considerations, scientific understanding of the natural environment, and genetic and biological mechanisms directly related to the conservation of the species.

ROLE OF NATIONAL PROGRAMS

Many supporting agencies, such as the Global Environment Facility (GEF) through the United Nations Environment Program (UNEP), World Bank, United Nations Development Program (UNDP), are available to assist countries in dealing with in situ conservation of rich and diverse nature resources. Few programs have been set up for in situ conservation of wild-crop relatives. A GEF-funded program has been undertaken in Turkey[2] for in situ conservation of the wild-crop relatives of wheat and legumes, wild fruit trees (Figs. 1, 2), and forest tree species at multiple sites in different ecosystems. This led to the development of a substantial national program to conserve wild-crop relatives in situ as genetic reserves. Other programs that have been conducted are for wild emmer wheat (Triticum dicoccoides) in Ammiad, Israel,[3] wild corn (Zea diploperennis) in the Sierra de Manantlan Biosphere reserve, Mexico,[4] and wild bean (Phaseolus lunatus) in Costa Rica.[5]

The conservation of wild species in genetic reserves, termed gene management zones (GMZs),[6] involves target species, site, policy, and socioeconomic parameters. Reserves are locations for the continuation of the evolution of plant populations with endangered and/or vulnerable as well as high and unique genetic diversity in their selected habitats.[6] Their number and size may vary. Reserves should consist of core, buffer, and, if necessary, transitional zones. A clear and detailed management plan is required to manage and maintain the genetic diversity of
target species, which interact with associated species at reserves. A national plan for in situ conservation can be developed to provide a mechanism for countries to set priorities and present a plan of action for effective designation, design, management of sustainable utilization, and monitoring of the reserves to ensure sustainable conservation in situ.[2] Detailed information about different parameters from different sources is required (Table 1) to achieve sustainable natural reserves. The use of geographic information systems (GIS) can aid in performing a spatial analysis of the data for selection, designation, management, and monitoring of genetic reserves.

**RESERVE DESIGNATION**

In the planning stage of in situ conservation, identification of key interventions is required: what species (either the most threatened or the already protected), which population, and which areas. Selection of target species should be objective, based on logical, scientific, and economic principles related to the perceived value of species. Many factors that provide a species with value have current conservation status; potential economic use; threat of genetic erosion; genetic distinction; ecogeographic distinction; natural, global, cultural importance; relative cost of conservation; and conservation sustainability.[2] Following the selection of target species or group of species, the biological, genetic, socioeconomic, and physical data about sites and target species should be collected by a series of ecogeographic and socioeconomic surveys and laboratory studies to assess the genetic diversity (Figs. 3–5).

Reserves should be accessible, suitable, and sustainable, and large enough to maintain a viable population size and biological interactions. The gene flow to target species from related species should also be considered.[6]

The species richness of the site is also important. If a keystone species has priority, its associated species can be maintained at the same reserve. The reserves can be established in either natural or seminatural habitats. Two or more reserves should be designated representing the ecological ranges of target species to support sufficient environmental heterogeneity.[2]

**RESERVE DESIGN**

The design of genetic reserves for in situ conservation, including questions about optimal size and shape, zonation and networking, has been discussed in various articles.[6–8] The reserves should be designed appropriately for target species. The reserve design involves consideration of various factors such as structure, size, number (either a single large site or smaller sites joined with corridors are sufficient for target species), reserve shape, environmental variability, and potential stakeholders and users. The currently agreed reserve structure is a central core with a stable habitat, surrounded by a buffer zone and outside this, where possible, a transition zone to protect the core population.[6,8] Practically, the majority of the wild relatives of crop plants are widely distributed and a single reserve would not be sufficient. But this is not always the case if species are naturally found in only one single area (Fig. 6).

Reserve size is critical to adequate and sustainable in situ conservation of plant species; therefore, the rate of species loss and genetic deterioration for most species is inversely proportional to the reserve size. Reserve size may vary according to the availability of resources as well as depending on the target species structure and nature. But it should provide a minimum viable population (MVP) size, minimum adaptive variation, and spatial multiniche flexibility to ensure the continued presence of target species. The suggested numbers of individuals in the reserves are in the range of 1000 to 5000. Effective population size should be considered (50 to 100 randomly sampled individuals) for assessment of the genetic diversity of the population.

The management plan for each genetic reserve should be developed to regulate human intervention and to ensure the maintenance of genetic diversity of target species populations. This plan should consist of the articulation of purpose, biological and genetic description of target species, physical description and biological environment of reserve sites, description of problems related to reserve, required management practices, and monitoring to assess the management effectiveness. Further intervention, grazing pressure, and harvesting should be included in...
the management plan.\[2\] Local community participation is also necessary. The conservation of plant species in many areas is likely to succeed if the area is yielding in some form of income to local people. But this should be applied in the buffer or transitional zones. Research should be conducted at the buffer or transitional zones.\[2\]

A comprehensive data management system incorporated with the GIS is required for each stage of in situ conservation program. All parameters given in Table 1 are necessary for effective reserve design. The spatial analysis generated by the process of conservation using GIS can provide feedback to enhance, facilitate, process, and add value to genetic resources conservation.\[2,9,10\] Finally, reserve design includes a means for monitoring population sizes and diversity over time and space so that modifications in design can be made as needed.

CONCLUSION

As a consequence of the extinction or decline of natural resources, in situ conservation in reserves should be mandated by national conservation programs. The establishment of genetic reserves recognizes the long-term objectives and the need for continued evolution with natural environments. Most of the in situ practices have been directed toward habitat preservation and have focused on ecological rather than genetic considerations. Genetic conservation goes further in recognizing the need for a wide genetic base. In situ conservation of wild species of plants is well recognized and more recently becoming an activity of national programs. There are few examples for conserving wild-crop relatives, which are in the gene pools of crop species. These examples can be a model for other countries to conserve national plant resources in situ. However, it is not always possible to propose in situ conservation strategies for all wild species occurring in different parts of the world with different characteristics, as there is still inadequate knowledge of their breeding systems, conservation biology, etc. To support a complementary approach between in situ and ex situ conservation, target species and associated species should be collected for ex situ conservation at gene banks.

In Situ Genetic Resource Conservation: Local Parks and Reserves

V. Arivudai Nambi
L.R. Gopinath
M.S. Swaminathan Research Foundation, Chennai, India

INTRODUCTION

The concept of “reserve” with regard to natural resources has been to set aside areas for exclusive current use as well as unperceived future uses. Precolonial states had several reserves where royalty protected valuable species like elephants, deer, teak, or sandalwood. Systematic and organized conservation efforts have largely been undertaken only in the last two centuries or so. Such conservation efforts closely followed conquest, expanding trade, commerce, and capital accumulation by colonial powers. Colonial expansion clubbed with the Industrial Revolution opened up the possibility of large-scale movement of raw material and goods from one region to another. What was considered inexhaustible resource at one point in time turned out to be exhaustible, leading to threats of scarcity. Such a threat led to the emergence of systematic and organized efforts at conservation of valuable resources.[1,2]

Conservation efforts can broadly be classified into the following: Managed in situ conservation was pursued through National Parks, Protected Areas, Biosphere Reserves, and World Heritage Sites while ex situ conservation was through botanical gardens and gene banks. The above are widely recognized efforts; conservation in the public domain, community conservation, or in situ on-farm conservation by rural and tribal women and men remain largely unrecognized (Fig. 1).[3,4] These communities continue to possess multifaceted traditional knowledge related to biodiversity, such as medicinal properties or food value of plants and animals.[3]

CONSERVATION STRATEGIES IN AGRICULTURE AND FORESTRY SECTORS

The last century saw worldwide conservation efforts that focused on a package of physical and biological entities such as soil, water, and individual species within ecosystems and excluded humans. The present century poses human societies with a formidable challenge: sustainable management of physical and biological resources where agriculture and forestry sectors move in opposite directions with regard to conservation. The agriculture sector has moved from the level of species to varieties and gene, while the forestry sector has moved from the level of species to ecosystem and landscape. A balance of competing interests of individuals and society in the multiple uses of natural resources is required.

Community conservation encompasses not only genetic resources such as landraces, folk varieties, cultivars, and breeds, but also ecosystems and landscapes in which sacred species, groves, and landscapes are embodied. There is a growing realization about the biodiversity-cultural diversity link and its importance. Changes in the social values with regard to traditional lifestyles, emerging new economies, livelihoods, and lifestyles have weakened community conservation to a significant extent. There is a pressing need to revitalize on-farm in situ conservation, as it is the key link between traditional knowledge, livelihoods, and lifestyles. Human beings always remained as managers of natural resources, through which they gained knowledge on animals, plants, climate, soil, and water and evolved various techniques and technologies for survival. This process continues to the present time. Communities living in hilly and inaccessible forested regions continue to hold traditional knowledge as well as generate new knowledge for the management of natural resources. It was through centuries of conservation and use by communities across continents that facilitated transfer of plants, such as rubber, tea, coffee, cotton, and groundnut to new locations for human use. The noted Russian scientist N.I. Vavilov undertook theoretical and applied work on economically important plants, to identify center of origin climatic analogies and wild relatives.

Since the Second World War, community-conserved genetic material was the feedstock for the crop varieties of the Green Revolution. The Green Revolution and the global environmental movement since 1960 together shaped conservation strategies for the domesticated and the wild species. With the passage of time, a number of global agreements were signed on realization that community-conserved genetic wealth
(domesticated and wild) and its associated traditional knowledge would leave more options for the morrow.

**ECOLOGY IN COMMUNITY CONSERVATION**

Species coexist under different relationships like competition, predation, parasitism, symbiosis, commensalism, and mutualism. Although humans are a part of this relationship, they have been able to control nature because of their intelligence. In the light of the above, community-conserved biological diversity has three important functions (Fig. 2): 1) ecological functions that maintain soil fertility and conserve water, leading to synchronized utilization of natural resources; 2) economic functions include food, fuel, fodder, timber, fiber, and medicine that contribute to local incomes both on-farm and off-farm; and 3) socio-functions that lead to diversity in resource use, tenures (private or public property), and social customs. Such relationships have a major impact on the demography of the region, political system, and social customs that are reflected in cultural diversity. Long-term sustainability of a species or diversity of species in a system depends upon the level of synergy among these three functions.

However, the economic function of a system assumes a vital role, since transactions among various social groups are determined by economics. The synergy of the above system is lost when there is a reduction in the economic function. A reduction in the local economy leads to direct negative environmental impacts that further reduce local biodiversity. It is within this context that institutions can contribute to biodiversity conservation.

**NATURAL RESOURCE MANAGEMENT: THE ROLE OF COMMUNITIES**

Although initial conservation at the species level largely excluded human activity, the establishment of national parks (Fig. 3) entailed some amount of inclusion of the human element. The evolution of the concept of the biosphere at the level of the landscape considers humans and their activities as part of nature. Such conservation efforts at the landscape level undertaken in the recent past have proved to be far more effective and sustainable.

In general, biosphere reserves act as havens for endangered animals and plants with a core zone in the center surrounded by buffer and transition zones. Traditional communities live in the core zone, and buffer zone depends on forest resources such as wild food, minor forest products, and traditional agriculture.
Buffer zone and the core zones are restricted in access to nonlocal people. The buffer zone withstands changes from inner core and the outer transition zones. The transition zone is sandwiched between the human modified modern industrial world and the buffer zone. It is this zone that assumes importance with regard to community conservation of crop genetic resources.

**AN INTEGRATED APPROACH TO CONSERVATION**

The biosphere concept considers humans as a natural component of the landscape, but there is no legal basis for its implementation. As a result, biosphere reserves share the rules and regulations of national parks, reserves, and sanctuaries as their management strategy. However, such overlap of different management strategies in the same region may lead to conflicts. Therefore, the concept of biosphere reserve needs more synchronized pathway for operationalization.

A multistakeholder approach trusteeship model and participatory conservation system (PCS) evolved by the M.S. Swaminathan Research Foundation (MSSRF) is an attempt to balance several issues addressed above through a process of share and care. This model is being implemented in the Gulf of Mannar Biosphere Reserve, a coastal aquatic system in southern India. For example, in the Gulf of Mannar Biosphere Trust in the Indian state of Tamil Nadu, MSSRF partners with the local communities; fisheries, forestry, and agricultural departments; research institutes such as the Central Marine Fisheries Research Institute to enhance sustainable harvest of natural resources. The activities in the area concentrate on providing land- and water-based income generation activities to local communities to reduce overexploitation of the bioresources of the Gulf of Mannar. Charcoal production, dairy farming, renovation of freshwater tanks are the land-based activities. Community-based agar production and pickled fish unit, creation of artificial reefs, and pearl culture are some of the marine-based livelihoods.

An integrated conservation strategy that combines in situ and ex situ conservation by blending traditional knowledge with modern conservation science should be developed in centers of high natural biological and agrobiodiversity. In situ conservation cannot be pursued without the component of traditional knowledge of communities associated with genetic resources. Moreover, given the present genetic erosion due to industrial agriculture, it makes practical sense to create agrobiodiversity sanctuaries in areas that are rich in agrobiodiversity and have a living traditional knowledge. In addition, eco-agriculture strategies[7] may be required to integrate at the landscape level agricultural and forestry concerns.

**CONCLUSIONS**

Natural systems are complex and multifunctional, providing differential services to different sections of the populations. While financial capital is crucial to the continued management of plant and animal genetic resources, social capital involving multiple stakeholders to manage natural capital at the landscape level is essential for sustainable natural resource management. This will be possible through a three-pronged strategy for the conservation and use of genetic resources: 1) regulations on conservation, enhancement, sustainable use, and equitable sharing of benefits; 2) social mobilization and community
participation in conservation, enhancement, use, and sharing of benefits; and 3) public education on the importance of conservation, enhancement, sustainable use, and equitable sharing of benefits.

ACKNOWLEDGMENTS

The authors wish to express their profound gratitude to Prof. M.S. Swaminathan, Chairman, who gave us an opportunity to write this entry and offered his valuable comments and suggestions on the paper and to Prof. P.C. Kesavan, Executive Director, M.S. Swaminathan Research Foundation, Chennai, for his constant encouragement and support and critical comments on an earlier version.

In Vitro Chromosome Doubling

V. Sarasan
Royal Botanic Gardens, Kew, Surrey, U.K.

A. V. Roberts

INTRODUCTION

Chromosome doubling occurs when a cell fails to divide into two daughter cells at mitosis. As a result, a single restitution nucleus is formed that contains the chromosomes that would normally have segregated to two daughter nuclei. A polyploid plant may emerge if the cell with doubled chromosomes develops into a complete plant. In nature, polyploid plants may be created by the spontaneous doubling of chromosomes in somatic cells or by the fusion of unreduced gametes. In the laboratory, it can be induced by the application of antimitotic agents to sporophytic or gametophytic tissues. Chromosome doubling also occurs when protoplasts of somatic cells are fused. This review focuses on the objectives of chromosome doubling, the use of antimitotic agents, and methods of detecting and isolating polyploidy variants.

POLYPLOIDY AND ITS ADVANTAGES

The chromosomes of a gamete are denoted by the letter \( n \), and the chromosomes in each genome of a gamete by \( x \). Thus, a diploid cell can be represented by the formula \( 2n = 2x \) and a tetraploid plant obtained by chromosome doubling by \( 2n = 4x \). Doubling the number of chromosomes of a tetraploid results in an octoploid \( (2n = 8x) \). Hybrids between diploid and tetraploid plants are triploids of usually low fertility. Doubling the chromosome number of a triploid results in a hexaploid \( (2n = 6x) \). A distinction is drawn between autopolyploids and allopolyploids on the basis of their origin and fertility.[1] An autopolyploid is derived from a fertile plant, such as a typical representative of a species, whereas an allopolyploid is of interspecific origin. An autopolyploid is typically less fertile than the original undoubled plant because, as each chromosome has more than one homologous partner, irregular pairing occurs at meiosis. An allopolyploid is usually fertile because chromosome doubling provides each chromosome with just one homologous partner and meiosis is regular. Allopolyploids benefit from a type of hybrid vigor, which results from the combination of the genes of two or more species. A well known example is evolution, in cultivation, of the bread wheat *Triticum aestivum*. This allohexaploid originated in two stages, each of which involved interspecific hybridization associated with chromosome doubling. First there was the formation of an allotetraploid from two diploid species and then an allohexaploid from the allotetraploid and another diploid species. There was an increase in vigor at each stage.

Although chromosome doubling of somatic cells and fusion of unreduced gametes are events that occur at low frequency in nature, as many as 80% of angiosperm species may be of polyploid origin.[1] The commercial importance of polyploids in agriculture and horticulture has led to the use of antimitotic agents that induce chromosome doubling in somatic cells by interfering with spindle formation. One common reason for inducing polyploidy is to obtain a fertile allopolyploid from a sterile hybrid. Another is to obtain a plant with the larger leaves, flowers, or fruits often associated with both autopolyploidy and allopolyploidy.

ANTIMITOTIC AGENTS

During cell division, chromosomes are segregated to opposite poles of a cell by spindle fibers. The spindle fibers are composed of microtubules that are formed rapidly at the onset of cell division by a process that involves the polymerization of \( \alpha \)- and \( \beta \)-tubulin polypeptides.[2] Antimitotic agents such as colchicine typically destabilize the microtubules and prevent new ones from forming. Consequently, the daughter chromosomes cannot segregate to opposite poles of the cell at anaphase. The two chromatids of each chromosome are initially held together at the centromere but eventually the association lapses, creating separate chromosomes. Cytokinesis fails to occur, leading to the formation of a restitution nucleus and a polyploid cell.
Colchicine was first used for chromosome doubling by Levan[3] and has been widely used for that purpose to date. However, in many species it is reported to cause undesirable effects such as sterility and abnormal growth.[4] More recently, chromosome doubling has been achieved with antimitotic herbicides, which prevent the synthesis or polymerization of the tubulin molecules into the microtubules of the spindle. Of these, the dinitroaniline herbicides oryzalin and trifluralin, the phosphoric amide herbicide amiprophos methyl (APM), and pronamide have been found to be effective in chromosome doubling.[5] Colchicine has a higher affinity for animal than plant microtubules but the reverse applies to the herbicides.

DETECTION OF POLYPLOIDS

The traditional method for assessing ploidy is by counting chromosomes in root meristematic cells. The recent method of flow cytometry[6] enables ploidy to be determined more rapidly and, as several thousands of cells can be assessed in a single leaf sample, cytochimerism can be detected more readily. Some morphological characteristics such as stomatal length, the number of chloroplasts in guard cells, and pollen grain diameter (which are often greater in tetraploids than diploids) can sometimes be used as indicators of ploidy. Other features that have been commonly noted following chromosome doubling include shorter stems, thicker and darker green leaf laminas with more serrated margins, thicker petioles, thicker stems with shorter internodes, and wider crotch angles (see references listed in Table 1).

STRATEGIES AND OBJECTIVES IN IN VITRO CHROMOSOME DOUBLING

Treatment of Sporophytic Tissues

Antimitotic agents can be applied to somatic tissues in vitro or in vivo. The treatment of seeds may be satisfactorily achieved in vivo by soaking germinating seeds in solutions of an antimitotic agent. There is a good chance the antimitotic agent will be imbibed when the seed swells and that it will reach the target tissue at a suitable concentration. However, the delivery of the antimitotic agent to the meristems of an established plant can be more difficult. In this event, in vitro culture is a widely used approach (Table 1). Delivery of the antimitotic agent may be easier through cut surfaces of an explant than through the protective cuticle of an in vivo plant. In some species, plants can be regenerated through adventitious shoots or somatic embryos after treatment, which greatly reduces the occurrence of cytochimerism.

If all cells in a meristem divided at the same rate, the optimum period of exposure to a spindle inhibitor would correspond to the cell cycle time. However, there are slow cycling cells that may remain undoubled and, therefore the duration of antimitotic agent application required for polyploidization must be determined empirically for each species. Compared to colchicine, oryzalin was found to be, for example, more phytotoxic to the leaves of *Actinidia delicosa*[7] and more efficient in inducing polyploidy in *Rhododendron*,[8] but reports on the relative merits of oryzalin and colchicine vary. Recent examples of chromosome doubling in sporophytic tissues are listed in Table 1.

(Data from Refs. 7–9 and 11–17.)
Treatment of Gametophytic Tissues

The major objective of chromosome doubling of gametophytic tissues is to produce homozygous dihybrids. These can be used as pure breeding parents and two homozygous lines can be hybridized to produce genetically uniform F1 hybrid seed. The more conventional method of producing pure breeding parents involves the slow procedure of selfing over about seven generations. Culture of haploids can be achieved through androgenic or gynogenic culture (Table 1). This can be combined with spontaneous or induced chromosome doubling to give dihaploids. The suitability of androgenic or gynogenic culture differs according to the species involved. In some species, regeneration is difficult to achieve in the presence of a chromosome-doubling agent. It may then be more efficient to first establish haploid shoot cultures to which antimitotic agents can subsequently be applied, as in gynogenetic cultures of *Allium cepa.*

Androgenic culture can be achieved by anther or microspore culture. Chromosome doubling may occur spontaneously or as a result of treatment with antimitotic agents. Adjustment of in vitro culture conditions may increase the frequency of spontaneous chromosome doubling. Gynogenic cultures may be obtained from unfertilized ovules. Haploids and dihaploid embryos may also be obtained by pollination with pollen of the same species that has been exposed to ionizing radiation, which disrupts normal chromosome function but permits pollen germination. This method was applied by Todorova et al. to sunflower. In gerbera, 76–100% of plants regenerated from unpollinated ovule cultures were haploid but treatment with colchicine resulted in 34% dihaploid plants. Oryzalin was found to be less phytotoxic than colchicine in doubling the chromosome number of gynogenic haploids of *Gerbera.*

CONCLUSION

The use of chromosome doubling for crop improvement has increased in the last decade because two crucially important techniques—plant tissue culture and flow cytometry—are now more widely available. It can be expected that this trend will continue as in vitro techniques, including those for adventitious regeneration, are successfully applied to recalcitrant species. As a method for crop improvement, interspecific hybridization linked with chromosome doubling has some advantages over the development of transgenic crops. It is a relatively low-cost technology, and can be used by small or large commercial enterprises with no public resistance. It is also likely that new applications of this technology will emerge in the future. Conservation of endangered species with reduced reproductive potential is an example. In *Ramosmania rodriguesii,* an endangered species,$^{[12]}$ staminal incompatibilities prevent fertilization and seed setting. Chromosome doubling of sporophytic tissues may in itself result in self-compatible plants. Alternatively, doubling of gametophytic tissues may result in dihaploids with the essential diversity of genotypes required for sexual compatibility.

INTRODUCTION

Flowering—the transition from the vegetative to the reproductive phase in plants—is an important developmental process with considerable biological and economic significance. Despite decades of research and rapid advances in technology, our understanding of this important developmental process is still fragmentary. From the results of previous research, it is evident that the majority of plants use environmental cues to regulate flowering. Environmental variables with regular seasonal patterns such as temperature, photoperiod, and irradiance are the key signals for floral transition. These factors are perceived by different plant parts, and strong and diverse interactions between the environmental variables are required for floral induction to occur in many species.

Classical physiological, genetic, and grafting experiments, although invaluable in deciphering various aspects of flowering, have failed to unravel the true nature of the flowering stimulus or the mechanism(s) by which various environmental cues induce flowering. Novel approaches involving in vitro and molecular techniques offer unique opportunities to investigate the flowering process from new perspectives. This article summarizes the major achievements of in vitro techniques in understanding flowering, and highlights the merits and future prospects of such approaches in resolving the questions surrounding floral transition.

ADVANTAGES OF IN VITRO FLOWERING

As compared to whole plant-based, in vivo experimental conditions, in vitro methods present several advantages to investigate flowering. They allow for much greater control of experimental conditions under investigation. For instance, precise and efficient application of different treatments and elimination of interfering factors can be achieved relatively easily under in vitro conditions. This ensures more reliable analysis of the role of growth regulators, nutrients, and environmental variables on flowering. Under tissue culture conditions, whole plants and individual plant parts (including isolated meristems) can be used for floral induction. In vitro cultures are more amenable to bioassays and model systems development than in vivo methods because growth conditions can be precisely controlled and monitored in culture. In vitro systems have been successfully used for the determination of molecular elements involved in flowering and reproductive development.[2] They can be exploited for in vitro breeding, which may reduce the breeding cycle considerably in perennial crops.

FACTORS INFLUENCING IN VITRO FLOWERING

Successful induction of flowering in vitro has been reported for numerous species from both monocotyledonous and dicotyledonous families. Considering the complexity of the regulation of flowering, it is not surprising that no common set of growth conditions exist that could be applied to in vitro floral induction in diverse species. From the available evidence, the key regulatory factors that induce flowering in vitro include photoperiod, irradiance, temperature, growth stage, and phytohormones. Besides these controlling factors, in vitro studies also showed that various nutrients, particularly nitrogen and carbon, and many nonhormonal bioactive compounds such as polyamines, jasmonates, and benzoic acid derivatives play a role in the regulation of vegetative to reproductive phase transition.

Phytohormones and In Vitro Flowering

Whereas there is no conclusive evidence to establish a particular compound as the master signal evoking floral transition under in vivo conditions, hormones in general are emerging as important factors regulating floral induction in vitro cultures in a large number of species.[3] As with any other developmental process, flowering in vitro is promoted by some hormones while inhibited by others. More intriguingly, in some species, the same hormone...
elicits contrasting flowering responses under different culture conditions.

Auxins in general do not promote flowering in vitro. However, there are examples of auxin-induced flowering in culture. For instance, *Pharbitis nils* seedlings grown in vitro could be induced to flower in noninductive conditions by the application of 2-naphthaleneacetic acid (NAA). Auxin also promoted flowering in *Perilla frutescens*, *Streptocarpus nobilis*, *Phlox drummondii*, and *Torenia fournieri*. Nonetheless, more evidence points to an inhibitory role for auxin in flower induction. Indeed, experiments with day-neutral tobacco cultures indicate that auxin has the potential to even revert the plants that are already in the reproductive phase to vegetative state. Working with *Torenia*—the most extensively investigated plant in relation to auxin involvement in flowering—Tanimoto and Harada concluded that auxin is unlikely to be a component of floral stimulus, although it promotes flower bud differentiation.

Among the different phytohormones, cytokinins are the most effective inducers of flowering in vitro. In most of the species tested, at least one cytokinin was required for flower induction and normal development of floral parts. It is important to note that in many species, for example, *Plumbago indica*, *P. frutescens*, and *Browallia demissa*, cytokinins were able to induce flowering in explants obtained from strictly vegetative plants maintained under noninductive conditions. Floral induction occurred only in a narrow range of cytokinin concentrations, and supraoptimal levels of cytokinin in the medium always resulted in vegetative bud formation in all the species investigated. Although the vast majority of the reports indicate a promotive role for cytokinin, it inhibited flowering in cultures of *Scrofularia arguta* and different cultivars of *Kalanchoe* and tobacco.

Different plant species require different types of cytokinins to induce flowering in culture. As an example, 6-benzyladenine is the most effective cytokinin for flower production in many orchids, bamboos, and passion fruit, whereas kinetin was more favorable than others for floral induction in *Arabidopsis* stem explants. In many species, however, a combination of different cytokinins or of cytokinin and auxin was needed for in vitro flower induction.

Gibberellins, the most potent florigenic compounds in vernalization-requiring plants, received much less attention in in vitro studies compared with cytokinins and auxins. Both promotive and inhibitory roles have been suggested for gibberellins with regard to in vitro flowering. Unlike cytokinins, there is little conclusive evidence to suggest that gibberellins evoke floral induction in vitro, as the explants used for floral induction studies involving gibberellin were derived from already flowering or florally-determined plants. Considering its importance in the development of reproductive structures, there is an obvious void of information about the inductive role of gibberellin in flowering of tissue-cultured plants.

Despite the fact that inhibitors have been implicated in the regulation of reproductive development, little work has been done on the action of abscisic acid (ABA) and ethylene on in vitro flowering. ABA induced flowering in vitro cultures of *T. fournieri* and *P. nils*, and markedly enhanced flower production in *P. indica* and *P. frutescens*. A close parallel between the endogenous ABA level and the ability to flower in vitro was noticed in *Torenia*. In this species, applied ABA inhibited flower bud formation in tissues taken from old plants, whereas a promotive effect on flowering was noticed in explants from younger plants.

**Nonhormonal Compounds and In Vitro Flowering**

Besides the known phytohormones, many bioactive compounds were found to have florigenic activity in vitro. The most significant ones are nicotinic acid, salicylic acid, benzoic acid, and coumaric acid.

Knowledge about the inductive role of mineral nutrients in in vitro flowering is limited. Investigations on *Torenia* found that low salt concentration and the absence of NH$_4$NO$_3$ were supportive of flowering in vitro. Nitrate appears to be the most florigenic of all the forms of nitrogen, and a high carbon:nitrogen ratio brings about flowering in some plants. In *Sinapsis alba* and *Cuscuta reflexa*, sucrose could induce or eliminate the requirement of high light intensity for flower induction, whereas even a brief removal of tobacco explants from glucose delayed flower formation.

**CONTRIBUTION OF IN VITRO STUDIES ON FLOWERING**

From the foregoing discussion it is evident that considerable effort has been expended to develop in vitro flowering systems for a large number of species. Many of these culture systems could be used to develop reproducible and sensitive bioassay systems to verify the role of chemical, biological, and environmental factors in controlling flowering. In addition, such systems are often the only ways to gain more insight into certain aspects of flowering, which are otherwise impossible to achieve in an in vivo environment. For example, experiments with florally determined tobacco and orchid plants have shown that determination to flower can be carried through from the flowering parent plant to the explant, and that it can persist for long periods in culture, often for several generations in orchids.
In vitro approaches provide unique opportunities to test and interpret the theories of the multicomponent model of flowering. To cite an example, it is almost impossible to verify the antagonistic effects exerted by the root on flowering without resorting to tissue culture systems. With appropriate experimental strategies, this aspect of flowering has been elegantly demonstrated in *Kalanchoe*, *Cichorium*, and sunflower.

The value of having a precisely defined and reproducible in vitro system to further our knowledge of flowering is best exemplified in the recent research by Yu and Goh on orchids.[2,5] They exploited a cytokinin-induced flowering system of *Dendrobium* orchid to investigate the profile of gene expression during flowering,[2] and identified three MADS-box genes of the AP1/AGL9 subfamily expressed specifically at the time of floral transition.[5] In addition, the *Dendrobium* in vitro flowering system allowed them to identify and characterize DOH1, a gene required for maintenance of basic plant architecture and floral induction.[6]

**IN VITRO FLOWERING AND PLANT BREEDING**

An in vitro system producing fertile flowers would be an invaluable breeding tool, especially for difficult-to-flower plants such as trees, bamboos, etc. In bamboo, which usually has 12 to 24 years of juvenile growth and is gregarious (i.e., all the bamboos in a local population flower simultaneously), the development of an efficient in vitro flowering system capable of producing viable seeds will be an important advancement in breeding this species.[7] A similar tissue culture system producing fertile flowers and viable seeds has been described for various orchids.

**CONCLUSION**

From the preceding discussion, it is apparent that in vitro flowering is not only an efficient approach to understanding various facets of flowering, but could also be exploited for practical applications. Considering the success obtained with numerous plant species, the development of an in vitro flowering system for most of the angiosperms is now within reach. The physiological and developmental status of the donor plant, composition and concentration of mineral salts in the medium, and presence of cytokinin are emerging as key factors controlling floral transition in culture. Clearly, in vitro systems are presenting unique opportunities to unravel the mysteries of flowering. With advances in molecular biology, remarkable progress in the molecular characterization of this developmental process can be expected in the near future.

INTRODUCTION

The capacity of cultured plant tissues and cells to undergo morphogenesis, resulting in the formation of discrete organs or whole plants, has provided opportunities for numerous applications of in vitro plant biology in studies of basic botany, biochemistry, propagation, breeding, and development of transgenic crops. Whereas the fundamental techniques to achieve in vitro plant morphogenesis have been well established for a number of years, innovations in particular aspects of the technology continue to be made. Tremendous progress has been made in recent years regarding the genetic bases underlying both in vitro and in situ plant morphogenesis, stimulated by progress in functional genomics research. Advances in the identification of specific genes that are involved in plant morphogenesis in vitro, as well as some selected technical innovations, will be discussed.

FUNDAMENTAL ASPECTS OF IN VITRO MORPHOGENESIS

The two primary morphogenic pathways leading to whole plant regeneration—which is a prerequisite for most plant breeding and genetic and transgenic applications of in vitro biology—involve either somatic embryogenesis, or shoot organogenesis followed by root organogenesis. Both developmental pathways can occur either directly without a callus intermediate stage, termed adventitious; or indirectly following an unorganized callus stage, termed de novo.[1] Few plant species have been shown to regenerate by both organogenic and somatic embryogenic pathways, but many plant species can regenerate by one or the other of these pathways.

Somatic embryogenesis may be the best example of totipotency expressed among a large number of plants.[2] Various culture treatments can be manipulated to optimize the frequency and morphological quality of somatic embryos, which are bipolar structures containing both shoot and root apices and developing in a manner parallel to that of zygotic embryos. Typical treatment factors include the plant growth regulator sources and concentrations, culture environment (including the physical form of the medium, e.g., liquid or semisolid; pH; humidity; light quality and quantity or absence of light; temperature; gaseous environment), and osmotic potential. Many of these factors must be adjusted (e.g., carbohydrates, nitrogen sources) or completely changed (e.g., withdrawal or reduction in auxin signal; perhaps an increase in other plant growth regulators such as abscisic acid; osmotic potential change to encourage desiccation) during maturation of somatic embryos, during which time they become competent for conversion into plantlets.[2]

Many of the same culture factors described above for somatic embryogenesis are also manipulated to induce and optimize organogenesis, but often these factors are manipulated in different ways.[3] For example, a high auxin signal (often specifically using 2,4-dichlorphenoxyacetic acid) is usually important to induce somatic embryogenesis, whereas a high cytokinin-to-auxin ratio (or high cytokinin with no auxin) is typically required to induce shoot organogenesis. Root initiation also typically requires a moderate to high auxin signal—but rarely use of 2,4-dichlorphenoxyacetic acid. Rather, a more “natural” source of auxin is used.[4] Because regenerated organs are unipolar, two distinct organogenic induction signals—one to induce shoots and the other to induce roots—are required to regenerate a whole plant. In contrast, bipolar somatic embryos are induced by a single induction signal.

GENETIC COMPONENTS OF MORPHOGENESIS

One of the most exciting advances in recent years is the discovery of specific genes involved in plant regeneration in vitro. Such genes are being explored in order to increase transformation efficiency and to develop marker-free transgenic plants.[4] Because a primary factor in optimizing somatic embryogenesis and organogenesis is phytohormone models, it is of interest that receptors for each of the major phytohormone classes have now been identified and many of the corresponding genes have been cloned.[4,5] Examples of specific genes involved in the major plant morphogenesis pathways are summarized in Table 1.
Genetic Aspects of Somatic Embryogenesis

Transgenic expression of the LEC2 (leafy cotyledon) gene (Table 1) is sufficient to initiate somatic embryogenesis with high viability but some abnormalities persist in morphology. Several genes appear to be involved in the vegetative-to-embryogenic transition, such as WUS (wuschel, or PGA6, plant growth activator), LEC1, SERK (somatic embryogenesis receptor kinase), and PT1 (primordial timing). SHR (short root) establishes the ground tissue through the first asymmetric cell division, CLV (clavata) and WUS interact to determine stem cell fate, and CLV and STM (shoot meristemless) regulate development of the shoot apical meristem. LEC1, ABI3 (abscisic acid-insensitive), and FUS3 (fusca) are involved in somatic embryo maturation.

Genetic Aspects of Shoot Organogenesis

CYCD3 is involved in the acquisition of competence for shoot regeneration, as is SRD3 (shoot redifferentiation) (Table 1). Shoot redifferentiation also involves SRD1 and SRD2. The vegetative-to-shoot organogenesis transition is promoted by ESR1 (enhancer of shoot regeneration). Two genes representing potentially independent pathways involved early in shoot organogenesis signal transduction include CRE1 (cytokinin receptor) and CKI1 (cytokinin independent). The shoot apical...
meristem stem cell identity is regulated by CLV and WUS,\(^9\) parallel to that observed in the shoot apical meristem of somatic embryos (described earlier). SIM and KNI (knotted) are involved in the function of the shoot apical meristem, and overexpression leads to the formation of ectopic shoot meristems.\(^{9,10}\) Other regulators involved in shoot apical meristem organization and lateral shoot formation include multiple SHO (shoot organization) and MGO (mgoun) genes.\(^9\)

**Genetic Aspects of Root Organogenesis**

Competition to regenerate root organs is affected by SRD2\(^{10,11}\) (Table 1). The transition of embryonic root cells to initiate vegetative growth is controlled by PKL (pickle).\(^7\) RML1 (root meristemless) and RML2 play specific roles in the root apical meristem,\(^11\) and interact with components of the apical dominance system.\(^{12}\) The RAC (rooting auxin cascade) gene is involved in an early stage of auxin perception specific to the formation of adventitious roots.\(^{11}\) and CYCD4;1 is directly involved in lateral root primordia formation.\(^{13}\)

**Genetic Aspects of Floral Organogenesis**

Floral organs arise as determinate structures out of the indeterminate shoot apical meristem.\(^9\) The concept of floral organs being specified by the A-, B-, and C-class genes is well established.\(^{14}\) LFY (leafy) is a key gene involved in the switch to reproductive growth and in establishing floral meristem identity.\(^9,14\) (Table 1). LFY activates the key A-class gene API (apetala), establishing the petals or outermost whorl of the floral organ.\(^{14}\) LFY and UFO (unusual floral organs) interact to control the B-class genes, with UFO providing regional specificity within meristems and thereby establishing the sepal whorl. LFY and WUS interact to control the C-class genes typified by AG (agamous), and the C-class genes interact with B-class genes to establish the stamens in the third whorl. C-class genes also act alone to establish the fourth or innermost whorl composed of carpels (because AG suppresses the action of WUS, thereby resulting in a suppression of the B-class components). Three MADS-Box SEP (sepellata) genes act as cofactors with the A-, B-, and C-class genes to convert vegetative leaves into floral organs.

**TECHNICAL INNOVATIONS**

In the past decade, many of the technical improvements resulting in improved in vitro plant regeneration systems have been related to manipulation of the gaseous and/or physical environment of the cultures. Falling outside this category are a few other noteworthy innovations pertaining to thin cell layer techniques and synthetic seeds.

**Manipulation of the Gaseous and/or Physical Environment**

Cultured plant tissues are known to interact with the culture medium and gaseous environment. Forced ventilation and use of ventilated culture vessels, for example, have facilitated optimization of in vitro morphogenesis systems, and high CO\(_2\) treatments have permitted establishment of photoautotrophic cultures.\(^{15}\) Control of the amount of ethylene released by the cultured tissues into the head space of the culture vessel—or alternatively, inhibition of ethylene synthesis or action—have led to improved morphogenic responses.\(^{16}\)

Efforts to improve bioreactor designs to facilitate economical large-scale production of plants or plant products have continued. Key issues that must be addressed with bioreactor designs for plant cell and tissue growth include aeration and minimization of shear damage. Advances in automation and computer controls have rendered bioreactor performance more reliable.\(^{17}\)

One of the most exciting developments in bioreactor design has been the temporary immersion system, which alternates immersion of the plant tissues in the liquid culture medium with exposure to the air space at timed intervals.\(^{18}\) Temporary immersion bioreactors have been demonstrated to improve yields of shoot proliferation cultures, microtubers, and somatic embryos, as well as improve the quality and vigor of the propagules with reduced frequencies of abnormalities and hyperhydricity.

Another interesting development is the use of perfluorochemicals and commercially stabilized bovine hemoglobin as gas carriers to enhance cell performance in liquid culture systems such as bioreactors. Perfluorochemicals are recyclable (can be used to deliver gases, then be recovered from the culture and recharged), and emulsion with the surfactant Pluronic F-68\(^8\) appears to synergistically enhance effectiveness. These gas carriers have been shown to improve cell division rates, stimulate biomass production, improve yields of cellular products, and enhance morphogenic totipotency.\(^{19}\) A technical innovation with a more physical impact on the culture environment is the use of semipermeable cellulose acetate membranes to enhance citrus somatic embryogenesis and particularly to normalize somatic embryo development.\(^{20}\)

**Applications of Thin Cell Layer and Synthetic Seed Techniques**

Thin cell layer culture, an approach involving mainly the manipulation of explant size to induce and optimize
regeneration, has been used for many years with dicotyledonous species to study in vitro morphogenesis. Thin cell layer cultures can be manipulated for rigorously controlled programming of different morphogenic responses: callus formation, shoot organogenesis, root organogenesis, floral organogenesis, or somatic embryogenesis.\[21\] In recent years the thin cell layer technique has been extended to a variety of species formerly considered to be recalcitrant to in vitro morphogenesis. Evidence is also gathering that thin cell layer techniques can be useful for recovering transgenic plants from species heretofore considered recalcitrant to genetic transformation.

There continues to be interest in developing synthetic seed technology based on artificial encapsulation of somatic embryos suitable for direct field sowing with reliable conversion into viable plants. The most important technical advances in this area involve the use of automated bioreactors to improve yields, combined with the use of computer imaging to sort out the somatic embryos possessing sufficient quality for encapsulation and subsequent conversion.\[22\] Even more exciting are the advances in use of nonembryogenic (unipolar) structures for encapsulation as synthetic seed.\[23\] There seems to be a lower risk of somaclonal variation using unipolar structures such as microbulbs; microtubers; rhizomes; corms; shoots; or nodes containing either apical or axillary buds, meristemoids, and bud primordia for encapsulation. Synthetic seed technology can be extended to a wider variety of genotypes.

**CONCLUSION**

Basic research has begun to dissect the complex genetic pathways involved in various aspects of plant morphogenesis, including all of the major pathways leading to in vitro plant regeneration. A number of candidate genes are being identified that can be expressed transgenically to enhance or even to initiate plant regeneration from cultured cells and tissues. Such genes are being explored for potential use in developing marker-free transgenic systems as well as to potentially enhance the frequencies of transgenic plant recovery.\[4\] These advances, as well as advances in specific culture systems such as thin cell layers,\[21\] offer the prospects of extending more efficient in vitro plant regeneration techniques to previously recalcitrant crops, and of developing more efficient genetic transformation methods. Such advances in controlling in vitro morphogenesis should play important roles at the applied level in developing new crop cultivars and reducing the cost of micropropagation, and in furthering basic research in the area of functional genomics by testing of transgenes in a wider array of plant species.

INTRODUCTION

Efficient regeneration of plants from cells and tissues through organogenesis is an important prerequisite for the successful application of biotechnology to crop improvement. In vitro regenerability is a highly variable genetic trait that can be introgressed into nonregenerating (recalcitrant) lines by conventional breeding. The availability of mutants with distinctive regenerative characteristics and the rapid developments in molecular biology have considerably advanced our understanding of the phenomenon of in vitro organogenesis in the recent past. While the last 10 years have seen remarkable progress in defining molecular mechanisms underlying plant processes, the specific area of organogenesis in vitro has not yielded many molecular secrets.

TOTIPOTENCY

The concept of totipotency is central to understanding in vitro regeneration. The term is used in the context of differentiation not being an irreversible process as a cell undergoes maturation, i.e., a living plant cell with overt functional and structural specialization still carries all the information necessary to divide and undergo a morphogenetic process in the form of either organogenesis [which can be either rhizogenesis (root formation), caulogenesis (shoot formation) or, occasionally, flower formation] or embryogenesis, or to develop directly into a specialized cell type (e.g., as seen in xylogenesis). It is clear, however, from observations of regeneration in even highly regenerative explants that not all living differentiated cells of an explant participate in the regeneration process. This may be due to: 1) an inability to achieve in vitro the necessary conditions for totipotent expression; 2) genetic (physical changes to chromosomes, e.g., loss of DNA or nucleotide substitution) or epigenetic (changes in DNA expression as a consequence of development, e.g., DNA methylation or the isolation of DNA into heterochromatin) blocks that interfere with the expression of totipotency; 3) the fact that not all cells are totipotent, i.e., although all cells may appear to be the same in a particular tissue, only some possess special characteristics that enable them to regenerate plants when isolated and cultured under inductive conditions.

The first step in the expression of totipotency, where it occurs, is for mature cells to reenter the cell cycle and resume cell division (a process known as dedifferentiation). The next step is redifferentiation, either through direct formation of organized structures (direct regeneration) or by the formation of an intervening callus stage from which organized structures may later be induced (indirect regeneration). An early appreciation of the mechanisms underlying regeneration of whole plants, or parts of plants, from cells came with the classic observations of Skoog and Miller[1] that the direction of differentiation could be influenced by the ratio of the exogenously supplied growth regulators auxin and cytokinin. They observed in tobacco stem pith cultures that a high ratio of auxin to cytokinin led to initiation of roots, whereas a low ratio led to development of shoots. Although there are many species for which this simple manipulation will not work, in principle, this is the basis for regeneration in plant tissue culture systems. The two groups of growth regulators play a pivotal role in unlocking and realizing totipotent expression by influencing both dedifferentiation and redifferentiation. Note, however, that other medium conditions such as nitrogen, carbon source, and pH are also extremely important.

The process whereby differentiated cells respond to inductive phenomena leading to organogenesis involves two major phases—competence and determination. These phases reflect the two-stage practice of exposing cultures first to an “induction” medium and then to a “regeneration” medium during the regeneration process,[2] although there are cultures for which both phases will occur on the same medium, particularly in the case of direct regeneration.

COMPETENCE

This is a transient state in which cells can be induced to follow an organogenic pathway[2,3] and mechanical wounding is the most effective biological trigger for shifting cells into the competent state. Competence can be thought of as having two distinct components, one for cell division and the other for organogenesis.
Competence for Cell Division

In order to sustain cell division following wounding, exogenous auxin (+/− cytokinin) is usually required. Progress in understanding the molecular basis of the action of auxins and cytokinins in the initiation and maintenance of cell proliferation has been slow, and the complex interaction between exogenously applied growth regulators—overlayed with the unknown of endogenous synthesis—makes it difficult to differentiate the individual roles of auxin and cytokinin.

Proteins known as cyclin-dependent kinases (Cdks) govern the onset of S-phase and mitosis in all eukaryotic cells and require an activating cyclin subunit, which leads to the formation of Cyclin/Cdk complexes. In particular, homologues of a 34 kDa protein kinase known as p34 (coded for by the Cdk CDC) have been found in all eukaryotes that have been investigated. Induction of the competence of transformed protoplasts to divide in the presence of auxin and, to a lesser degree, cytokinin, was shown to be accompanied by expression of the Arabidopsis CDC2a gene, even if there was no subsequent cell division,[4] and led to the proposal of a linkage between the expression of CDC2a and competence for proliferation. A role for the Arabidopsis gene SRD2 in conferring competence for cell division has been hypothesized[5] and the expression of CDC2a in the srd2 mutant is being undertaken. At another level of complexity, the gene AINTEGUMENTA (ANT) has also been implicated in cell cycle progression, but in addition it influences organ growth.[6] Ectopic expression of the gene gives rise to transformed plants that show spontaneous callus formation and regeneration (of roots, leaves, or shoots) at wound or senescence sites. Seen as a gene that maintains meristematic competence in cells, ANT could give a molecular basis to the frequent observation in tissue culture that explants derived from immature tissue (such as from embryos) are much more likely to succeed in producing regenerable cultures than those obtained from mature tissue. In other words, competence in vitro may be correlated with continuing meristematic activity in vivo.

Competence for Organogenesis

A gene in Arabidopsis (IRE1) that acts very early in dedifferentiation confers the ability of cells to respond later to specific regeneration stimuli such as auxin and cytokinin.[7] The work of Ozawa et al.[5] with Arabidopsis mutants srd1, srd2, and srd3, which are defective in their ability to regenerate, identified three sequentially acquired states associated with organogenic competence. Initially there is IC (incompetent with respect to both cell proliferation and organogenesis), which requires the gene SRD2 in order to progress to CR (competent with respect to rhizogenesis). Finally, SRD3 is involved in the progress from CR to CSR (competent with respect to shoot and root organogenesis).

DETERMINATION

This is a process in which cells follow a specific developmental pathway. The distinction between determination and competence can be illustrated by the work of Christianson and Warnick.[2] They found that callus produced on Convolvulus explants was initially developmentally interchangeable, i.e., it was competent to follow two developmental pathways—root formation and shoot formation. Once induction of shoots began, the cells involved in shoot formation became determined, and transfer to a root-inducing medium did not affect the formation of shoots. In other words, as determination proceeds, cells become more and more committed, and the developmental potential becomes restricted unless there is a catastrophic event—such as wounding—that cuts across the determined state. The realizing of commitment is considered to be a third phase in the process of organogenesis.[2]

In the Skoog and Miller model,[1] caulogenesis is stimulated by exogenous cytokinin. The work of Ozawa et al.[5] indicated that the genes SRD1 and SRD2 play essential roles in the caulogenesis induced by culturing competent explants on a medium containing cytokinin. Three genes, CKI1 isolated from Arabidopsis,[8] ESR1 isolated from Arabidopsis,[9] and PkMADS1 isolated from Paulownia,[10] have been identified as regulators of shoot regeneration. CKI1 is thought to function as a cytokinin receptor in the process of cytokinin induction of shoot organogenesis. ESR1 expression is induced by cytokinins, but transcripts of the gene accumulate only after acquisition of organogenic competence. PkMADS1 is hypothesised to be a shoot meristem identity gene whose expression is necessary in activating the developmental pathway leading to direct regeneration of shoots. Cytokinin also induces another shoot meristem gene, PASTICCINO, but the outcome is an inhibitory one that prevents excessive cell proliferation,[11] thus eliminating abnormal shoot development. The expression of homeobox genes in plants can be induced by cytokinin, and two such genes—KNOTTED1 and STM (SHOOT MERISTEMLESS)—have been implicated in shoot formation.[12]

The most frequent type of regeneration occurring in cultured cells is root formation, and this is stimulated by auxin.[11] However, there is some complexity in the action of auxin, because although it stimulates root initiation, its continued presence in the culture medium can inhibit the outgrowth of roots. Experimental systems looking at the molecular basis of rhizogenesis are few and deal almost exclusively with lateral root formation and the
development of adventitious roots on stem cuttings. Lund et al.,\textsuperscript{13} working with a tobacco root mutant (\textit{rac}) that fails to initiate adventitious roots in response to exogenous auxin, concluded that the \textit{RAC} gene is involved in an auxin signal transduction pathway acting prior to the first organized divisions that lead to the formation of root meristems. During the determination phase of rhizogenesis the \textit{LRP1} (LATERAL ROOT PRIMORDIUM) gene is expressed,\textsuperscript{14} and during both determination and commitment certain S-adenosylmethionine synthetase-encoding genes (SAMS) are also up-regulated.\textsuperscript{15} The \textit{Agrobacterium rhizogenes} infection system is a potentially useful tool for characterizing events in rhizogenesis. Cells infected with the bacterium show an increased sensitivity to auxin, consistent with the ability of such cells to undergo root meristem neoformation and proliferation.

\section*{CONCLUSION}

Regeneration through organogenesis represents an amazing developmental plasticity that sets plant cells apart from most animal cells. It is an extraordinarily complex phenomenon influenced by an array of internal and external factors. The molecular work to date suggests that there is certainly no single “totipotency” gene, and the existence of a conserved suite of genes that defines a group of cells as organogenic or recalcitrant in vitro is not very evident either.

INTRODUCTION

Pollination followed by fertilization normally leads to the production of an embryo that, in the intact plant, is linked with normal seed development. Most angiosperms are outbreeders, as such self-pollination (selfing) is limited. Furthermore, hybridization between species and/or genera is also rare in nature. In plant breeding, however, selfing and hybridization are methods commonly used to obtain desirable crosses. If no fertilization takes place after self- or cross-pollination, plant breeders resort to special procedures such as in vitro pollination to bring about fertilization.

In vitro pollination and fertilization is a technique wherein male and female gametes are isolated and introduced to each other under conditions suitable for zygote formation. It involves pollen tube penetration of the embryo sac via manipulation of maternal tissue by methods other than the normal in situ process. Initially developed to bypass prezygotic incompatibility barriers, this technique has been used for the production of hybrids, the induction of haploid plants, overcoming sexual self-incompatibility, and in the study of reproductive processes and pollen physiology. The diversity of applications is mirrored by the diversity of species to which this technique has been applied.

IN VITRO POLLINATION AND FERTILIZATION

Indian scientists Kanta, Rangaswamy, and Maheshwari[2] led the first successful forays into the concept of in vitro pollination and fertilization. By 1962 they established methods for the in vitro pollination and fertilization of *Papaver somniferum* (opium plant). Successful in vitro pollination and fertilization is dependent on several basic elements,[3] including: 1) use of pollen grain and ovules at the required developmental phase; 2) sufficient pollen germination; 3) appropriate growth of pollen tubes and correct gametogenesis (sperm development); 4) pollen tube penetration into ovules; 5) successful fertilization; and 6) appropriate nutrient media (to support pollen germination, pollen tube growth, fertilization, and embryo development).

In vitro pollination and fertilization has been most successful in species such as those belonging to the *Papaveraceae*, *Caryophyllaceae*, and *Solanaceae*, whose ovaries are large, contain many ovules, and are situated on nutrient-rich placenta.[4] Compared to in vivo methods, in vitro pollination and fertilization offers increased control of environmental conditions, and thus enhances the accuracy and repeatability of experiments.

Types of In Vitro Pollination and Fertilization

There are three main methods of in vitro pollination and fertilization, each suitable for slightly different purposes. Successful application of a method to one species or family does not guarantee its successful use in another species or family.

In vitro stigmatic pollination and fertilization

In this method, pollen from an externally sterilized ripe anther is placed on the stigma of an emasculated flower. This technique is suitable for plants with premature ovary loss. *Nicotiana rustica*, *Nicotiana tabacum*, *Pisum sativum*, and *Zea mays* are examples of species in which this technique has been successful.[5]

In vitro placental pollination and fertilization

In this technique, placenta from explants with unfertilized ovules are dissected from an externally sterilized flower, onto which pollen grains are placed. Because this method has worked well with certain species of *Brassica*, it is thought that in vitro cross-pollination could be successfully applied to all members of the Brassicaceae to avoid pollen/pistil incompatibility.[4] This method has also been used successfully on members of the Caryophyllaceae and *Zea mays*. Most important, in vitro placental pollination and fertilization can sometimes be achieved with plants...
(such as *Petunia axillaris*) that are completely self-incompatible in vivo.\[6\]

**In vitro ovular pollination and fertilization**

Both cross-pollination and self-pollination can be achieved using this technique, in which pollen is applied to excised ovules from an externally sterilized flower. Selected ovules must be suitable for pollination by their own or foreign pollen. Success with this technique has been seen in *Cichorium intybus* L.\[7\] and various species of Brassicaceae.\[8\]

**PRACTICAL APPLICATIONS**

There are many practical applications of in vitro pollination and fertilization. These techniques often allow barriers to pollination and fertilization to be overcome, achieving cross-pollination/fertilization and self-pollination/fertilization where it is impossible to realize these objectives in vivo. This method has the potential to aid in the rescue of endangered species by overcoming incompatibilities, and in the creation of higher-quality commercial products through development of hybrids. It also enables further study into the process of fertilization, and the physiology of pollen.

**OVERCOMING INCOMPATIBILITY BARRIERS (SELF-INCOMPATIBILITY AND INTERSPECIFIC INCOMPATIBILITY)**

Incompatibility barriers can be classed as prezygotic (occurring prior to fertilization) and postzygotic (occurring after fertilization). Prezygotic incompatibility factors include those that impede effective fertilization (e.g., failure of pollen to germinate and penetrate the stigma, disintegration of the pollen tubes in the style, inadequate length of pollen tubes to effect fertilization). Circumventing prezygotic barriers by using in vitro techniques does not rule out the existence of postzygotic barriers to success in achieving the desired cross.

Postzygotic barriers occur during or immediately following syngamy (union of gametes during fertilization), and result in embryo starvation and abortion due largely to abnormal endosperm development.\[9\] When used in tandem with embryo culture techniques, in vitro pollination and fertilization can overcome sufficient incompatibility barriers to produce viable seeds and whole plants. Overcoming incompatibility barriers will potentially lead to the production of better commercial plant products, and could assist in saving endangered species.

Self-incompatibility or interspecific incompatibility is often manifested in pollen/stigma or pollen/style rejection responses, which can be bypassed through use of in vitro pollination and fertilization techniques. In vitro placental pollination and fertilization enabled Zenkteler et al.\[8\] to bypass pollen/stigma self-incompatibility in *Brassica campestris*. In vitro ovular pollination and fertilization was the technique used by Rangaswamy and Shivanna\[6\] to overcome self-incompatibility in *P. axillaris*.

**PRODUCTION OF HYBRIDS**

In vitro pollination and fertilization, particularly when used in conjunction with embryo culture techniques, enables incompatibilities to be overcome, which allows interspecific, interfamiliar, and intergeneric hybridization where conventional crossing techniques fail. Combining in vitro pollination and fertilization with new pollination methods, such as in vitro cut-style pollination and in vitro grafted-style techniques,\[10\] has the potential to overcome even greater incompatibilities than those overcome by the use of in vitro pollination and fertilization alone. The combination of in vitro pollination and the grafted-style method (GSM) has successfully overcome hybridization barriers between several incongruent lily species.\[10\]

Stylar barriers preventing hybridization (in particular, *Nicotiana* interspecific combinations) have been overcome by use of in vitro pollination and fertilization.\[9\] In vitro placental pollination and fertilization enabled Zenkteler et al.\[8\] to obtain hybrids between *Brassica napus* and *B. campestris*. Hybrids between *Brassica chinensis* and *Brassica pekinensis* were obtained using in vitro ovular pollination and fertilization.\[11\]

**INDUCTION OF HAPLOID PLANTS**

Haploid parthenogenesis can be induced by pollination with pollen of unrelated species or with inactivated pollen from the same species.\[7\] *Melandrium album* (used as the female plant) can be pollinated with pollen from species of *Nicotiana* to obtain 1% haploid plants.\[4\]

**STUDYING REPRODUCTIVE PROCESSES AND POLLEN PHYSIOLOGY**

In vitro methods offer new ways to study plant reproductive processes and pollen physiology. The development of an in vitro fertilization method without the application of electrical pulses for higher plant gametes could be used...
for studies of cell-cell interaction (adhesion, fusion, recognition). Haldrup and Bruun showed that in vitro pollination could be employed to study the time course of, and processes related to, pollen-tube development. Rougier et al. predicted that in vitro fertilization systems (readily available for studying the processes of zygote formation in flowering plants) may provide new tools for molecular analysis of fertilization and early embryo development. In vitro pollination has been used as a model for the study of fertilization in Z. mays.

CONCLUSION

The basic concept of in vitro pollination and fertilization has evolved to be applied to various components of the pistil, and to be adapted to an enormously diverse range of plant species.

In vitro pollination and fertilization is a technique that has been used for the production of hybrids, the induction of haploid plants, overcoming sexual self-incompatibility, and the study of reproductive processes and pollen physiology. Although its potential has not yet been fully explored, in vitro pollination and fertilization has already assisted in the conservation of endangered species and in the creation of new hybrids. In vitro pollination and fertilization will almost certainly result in the development of stable novel genotypes of economically superior plants, the most important of which are edible crop species. Greater genotypic variation could mean decreased disease susceptibility and increased crop survival in inhospitable climates—very desirable traits for crop improvement.

In this era of genetic engineering, in vitro pollination and fertilization represents an essential tool with which to gain a deeper understanding of the mechanisms of fertilization in plants and the physiology of pollen. In vitro pollination and fertilization undoubtedly has a role to play in the search for genes affecting pollination and fertilization in Arabidopsis, the recently sequenced model plant.

In the future, in vitro pollination and fertilization will be used in conjunction with myriad techniques of cell engineering to aid researchers in their quest to better understand the mysteries of plants.

In Vitro Production of Triploid Plants

Sant S. Bhojwani
University of Delhi, Delhi, India

INTRODUCTION

Most of the flowering plants are diploid with two sets of chromosomes. The plants with a higher number of chromosomes are called polyploids. Many spontaneous and induced polyploid varieties of crop plants are under cultivation because of their better vigor, improved fruit size/quality, and/or attractive flowers or foliage. The triploid plants, with three sets of chromosomes, are seed-sterile due to disturbance in gamete formation. Therefore, triploids hold great commercial potential where seedlessness is desirable or is of no serious consequence. Triploid varieties of banana, citrus, hops, and watermelon are already under commercial cultivation for their seedless fruits. Some natural triploids of tomato bear larger and tastier fruits than their diploid counterpart. Triploidy is of special significance for crops, which are grown for their vegetative parts or flowers. Some examples where triploids have proved superior to their diploid or tetraploid counterparts for a specific economic trait are high-yielding cassava (IPGRI Newsletter for Asia, the Pacific and Oceania, May–August, 2001), disease-resistant mulberry, more vigorous and ornamental petunia, and poplar with more desirable pulpwod.

The natural occurrence of triploids is very rare. On the other hand, the traditional method of artificial production of triploids is tedious and lengthy. It involves treating the diploids with colchicine to raise tetraploids, with four sets of chromosomes, followed by backcrossing the superior tetraploids with the diploids. In many cases, this is not possible due to sexual sterility of the tetraploid plants or failure of the cross. In contrast, in vitro regeneration of plants from endosperm, a natural triploid tissue, offers a direct, single-step approach to raising triploids. The sexually sterile triploids can be multiplied by micropropagation.

ENDOSPERM DEVELOPMENT

The angiosperms are characterized by double fertilization. During sexual reproduction, the male gametophyte delivers two sperms in the female gametophyte. Of these, one sperm fuses with the egg, which forms the well-organized diploid embryo, whereas the other sperm fuses with two nuclei in the central cell, which gives rise to an unorganized endosperm tissue. Since the endosperm is derived from the fusion product of three haploid nuclei, it is triploid. It is the main source of nutrition for the developing embryo. In some plants (pea, orange, and watermelon) the endosperm is completely consumed before seed maturation, whereas in others (castor bean, maize, and coconut) it persists in mature seeds as a massive tissue and supports the growth of the embryo during seed germination.

ENDOSPERM CULTURE

Following the discovery of double fertilization around 1898, the embryologists regarded endosperm as a second embryo modified to serve as a nutritive tissue for the zygotic embryo. Sargant remarked that the triploid nature of the endosperm might be responsible for its formless structure. However, the in vitro studies have clearly demonstrated the ability of the endosperm tissue for unlimited growth and to regenerate full plants.

The work on endosperm culture was initiated in 1933, but the establishment of continuously growing tissue cultures of maize endosperm was first achieved in 1949, by LaRue. Although maize endosperm persists in mature seeds, callus cultures could be established only from immature endosperm; 8–11 days after pollination (DAP) was the best stage. This is also true for other cereals, where the bulk of the mature endosperm is dead. Thus, the age of the endosperm at the time of culture could be a critical factor in raising tissue cultures of some species.

In 1963, Mohan Ram and Satsangi demonstrated that divisions could be induced in mature endosperm cells of castor bean by treating the seeds with 2,4-dichlorophenoxyacetic acid (2,4-D) before germination. In the same year, establishment of continuously growing callus cultures from the mature endosperm of sandalwood was reported by Rangaswamy and Rao. Since then, it has been possible to initiate tissue cultures from mature and immature endosperm of many plants. A critical factor in the induction of cell divisions in mature endosperm is its initial association with the embryo. There is ample evidence to suggest that the germinating embryo contributes some factor, which is essential to trigger cell divisions in the mature endosperm. The mature endosperm from dried seeds was shown to be able to induce callus formation in vitro.
seeds of castor bean did not callus, but if the seeds were soaked in Ca(OCl)₂ solution 22 hours prior to the excision of the endosperm, it exhibited callusing. The frequency of callusing increased if the seeds were allowed to germinate, and the number of cultures showing proliferation was directly related to the germination period before the excision of the endosperm. For tomato, soaking the seeds for three days was optimum in terms of the number of cultures showing endosperm callusing. Therefore, to initiate callus cultures from mature endosperm, it is cultured along with the embryo intact, and once the endosperm callusing has initiated (after 7–8 days) the embryo is removed to ensure that it does not callus and contaminate the endosperm callus. In some plants, the embryo factor could be substituted by gibberellic acid (GA₃). Although it is now possible to induce divisions in mature endosperm of many species (castor bean, croton, jatropha, putranjiva, neem, and sandalwood), immature endosperm continues to be the explant of choice in cereals and in those species where endosperm is consumed before seed maturation (acacia, citrus, cucumber, and mulberry).

The maize endosperm callus grew best on a medium containing yeast extract. However, in most other systems an auxin (generally 2,4-D), a cytokinin, and a rich source of organic nitrogen (yeast extract or casein hydrolysate) are required for optimal growth. The callus can be multiplied for unlimited period by periodic subcultures.

**PLANT REGENERATION**

By 1964 the cellular totipotency of plant cells had been well established, but the endosperm cells were still

regarded as recalcitrant for plant regeneration. In 1965 Johri and Bhojwani, [8] working with Exocarpus cupressiformis, first reported the differentiation of well-organized shoot buds from the mature endosperm. Histological studies confirmed the origin of the shoots from the peripheral cells of the endosperm (Fig. 1). As expected, the shoots were triploid. Since then, shoot/embryo/plant regeneration from the endosperm tissue has been reported for at least 24 species (Table 1).

In the cultures of mature endosperm, shoot differentiation may occur directly from the endosperm or after callusing. However, in immature endosperm cultures, it is always preceded by a callus phase. Plant regeneration from the callused endosperm of acacia, citrus, and sandalwood occurred via somatic embryogenesis.

For shoot bud differentiation from endosperm tissue, a cytokinin is always essential. Whereas Scurrula pulverulenta and Taxillus vestitus differentiated shoots in the presence of a cytokinin alone, Dendrophthoe falcata and Leptomeria acida required an auxin in addition to a cytokinin. The immature endosperm of mulberry (17–20 DAP) exhibited good callusing on a medium containing 5 μM 6-benzylaminopurine (BAP) and 1 μM α-naphthaleneacetic acid (NAA). Further addition of coconut milk and yeast extract improved the callusing response. The initial association of the embryo was promotive for endosperm callusing. The callus differentiated multiple shoots when transferred to a medium containing BAP or thidiazuron. However, maximum regeneration occurred when BAP was added in conjunction with NAA[21] The endosperm callus of citrus initiated on a medium containing 2,4-D (2 mg hr l⁻¹), BAP (5 mg hr l⁻¹), and casein hydrolysate (1000 mg hr l⁻¹) differentiated globular embryos upon transfer to a medium with GA₃ (1 mg hr l⁻¹) as the sole hormone.[13] Further development of the embryos and plant regeneration required doubling the salt concentration and raising GA₃ concentration to 15 mg hr l⁻¹. In Taxillus vestitus, injury to the endosperm enhanced shoot bud differentiation (Fig. 2).

Most of the organs and plants regenerated from endosperm are triploid. Full triploid plants of endosperm origin have been developed for apple, kiwifruit, mulberry, neem, and sandalwood. The triploids of mulberry and sandalwood have been established in soil.

CONCLUSION

There is enough experimental evidence to suggest that endosperm cells are totipotent, and the technique of endosperm culture holds great potential in raising triploids of crop plants. Endosperm culture from crosses of selected diploid parents is likely to give better triploids. Triploid plants of Petunia axillaris derived from cultured microspores were much more ornamental than their parental anther-donor diploids.[29]

In Vitro Tuberization

Yasunori Koda
Hokkaido University, Sapporo, Japan

INTRODUCTION
Various plants such as potato, yam, and Jerusalem artichoke develop tubers as organs for reproduction. When nodal stem segments of these plants are cultured aseptically in vitro under appropriate conditions, in vitro tubers are formed synchronously on lateral shoots that emerge from the nodes. Tubers formed in vitro are usually called microtubers. The culture system has provided a useful mechanism for various basic studies related to storage organ formation. In this article, in vitro potato tuberization is mainly described, with regard to the factors affecting the process, the mechanism, and a simple method of induction.

TUBERIZATION IN THE FIELD
After the first report by Barker on potato tuberization in vitro,[1] the culture system has been used in various basic studies. The nature of tuberization in the field is described first, since there are several analogies between tuberization in vitro and in the field. Tuberization in field-grown plants is controlled mainly by photoperiod. Short days stimulate the process, whereas long days prevent or retard it. The response to photoperiod interacts with many other factors. Both high temperature and high levels of reduced nitrogen in the soil inhibit tuberization. Plants from physiologically old mother tubers form tubers irrespective of photoperiod, so aging makes the photoperiod requirement for tuberization redundant. As to the genotype, late-maturing cultivars have a shorter critical photoperiod than the early-maturing cultivars. In other words, tuberization occurs earlier in the early-maturing cultivars under the natural field conditions from summer to autumn. The differences in their tuberizing ability seems to be due to the balance between two endogenous factors, one being inhibitive and the other promotive. The inhibitive factor is gibberellin (GA) and promotive one seems to be jasmonates (jasmonic acid, JA, and related compounds).[2] GA that is necessary for formation and elongation of stolon strongly inhibits tuberization, and reduction of GA level is a prerequisite to tuberization.

Potato tuberization is initiated by expansion of cells at the subapical region of a stolon, i.e., a kind of lateral shoot. The swelling at this early stage is mainly caused by radial expansion of cells. Subsequently, vigorous thickening growth due to expansion and division of cells occurs, and starch accumulates. The initial cell expansion is attributed to both an increase in osmotic pressure in the cells due to the accumulation of sucrose and changes in cell wall architecture that increase extensibility of the wall. The direction of cell growth (elongation or expansion) is controlled by the orientation of cortical microtubules (MTs). Characteristic reorientation of MTs, from perpendicular to parallel with respect to the axis of the stolon, is found when a slight swelling of the stolon occurs. Jasmonic acid (JA) is capable of inducing both reorientation of MTs and expansion of cells.[2] After the commencement of the swelling, cytokinins are accumulated in the expanded region, leading to cell division.

FACTORS AFFECTING IN VITRO TUBERIZATION
Various factors affecting in vitro tuberization are summarized in Table 1. Each factor exhibits the opposite effect on shoot growth. Longer duration of culture period tends to stimulate tuberization. The low tuberizing ability of late-maturing cultivars seems to be partly due to higher endogenous GA.[3] Application of an inhibitor for GA biosynthesis, such as ancyimidol, uniconazol, or paclobutrazol at concentrations below 10 μM, stimulates in vitro tuberization in late-maturing cultivars. JA is also capable of inducing microtubers in these cultivars, but it induces only smaller tubers.

Sucrose at a high concentration (more than 6%) is indispensable for in vitro tuberization. Although the supplied sucrose is rapidly hydrolyzed into glucose and fructose, these monosaccharides cannot replace sucrose,[4] indicating that sucrose is not a mere regulator of osmotic pressure. Cytokinins (benzyladenine, kinetin, and zeatin, etc.) at a concentration of 10 μM can promote tuberization.

Culture conditions, such as vessel size, headspace gas exchange, and culture density, affect in vitro tuberization and yield of microtubers. Although a large-scale bioreactor with forced aeration is favorable for good yield, the
system itself affects the cost of seed tuber production. A vessel that contains a smaller amount of medium (e.g., a 500 ml bottle containing 50 ml medium) can produce enough microtubers. When the bottle is sealed tightly with aluminum foil, many lenticels are formed on the surface of the microtubers, reducing their storability. Lenticle formation seems to be mediated by ethylene production, because an application of silver thiosulfate (ethylene antagonist) to the medium or sealing the culture vessels with air-permeable membrane can reduce lenticel formation. The density of shoots in the culture also affects microtuber production; usually, the larger the density, the higher the rate of production.

**MICROTUBER DORMANCY**

Prolonged or highly variable dormancy is a significant obstacle to the efficient use of microtubers as seed tubers. The dormancy seems to be induced by endogenous abscisic acid (ABA) and/or ethylene. Microtubers that developed in the presence of fluridone (an inhibitor for synthesis of carotenoid including ABA) or silver nitrate (ethylene antagonist) exhibit a loss of dormancy and sprout on the mother shoots (precocious sprouting). On the other hand, GA can release tubers from dormancy. Varying photoperiodic treatments and light intensities during the microtuber induction affect the duration of dormancy. The lower the light intensity, the longer the dormant period. An 8-hour photoperiod instead of continuous darkness reduces dormancy. Although several exogenous chemicals could break dormancy, chemical treatments sometimes affect the growth of plants developed from microtubers. Rindite and bromoethane have a practical use as dormancy-releasing regents. The duration of dormancy can be manipulated by various methods, but development of cultivar-specific protocols is necessary to control dormancy.

**A SIMPLE METHOD FOR IN VITRO TUBERIZATION**

An in vitro tuberization system can be established easily from tubers using the procedure shown in Fig. 1. This system is based on the principle that microtubers can be induced to develop into shoots under specific conditions. The following factors are considered important for successful in vitro tuberization:

- **Environmental Factors**
  - **Photoperiods**: Short days (Promotive) vs. Long days (Inhibitive)
  - **Temperature**: Cool (20–22°C) (Promotive) vs. Warm (25°C) (Inhibitive)

- **Nutritional Factors**
  - **Sucrose**: High (8%) (Promotive) vs. Low (3%) (Inhibitive)
  - **Reduced nitrogen** (Inhibitive vs. Promotive)

- **Genotypic Factors**
  - **Early-maturing cultivars** (Promotive) vs. **Late-maturing cultivars** (Inhibitive)

**Fig. 1** Schematic diagram showing the procedure to establish an in vitro tuberization system from potato tubers.
method enables one tuber to produce many nodal segments as materials for culture, and is also applicable to bioassay for tuber-inducing activity. Surface-sterilization of tubers and tissue plugs is necessary to avoid microbial contamination, and relative humidity in the dark room should stay below 30% in order to raise healthy etiolated shoots. After surface-sterilization, nodal segments of the shoots are planted on agar-solidified Murashige–Skoog (MS) medium (3% sucrose) and cultured at 25°C for 2 to 3 weeks to obtain lateral shoots. If some tuber-inducing compound such as JA is applied to the medium, tubers are formed on the laterals. To produce microtubers routinely, two culture steps are usually employed (Fig. 2). The first step is called in vitro layering, which involves shoot propagation by recycling segments of shoots back to the shoot culture. Vigorously growing shoots are selected and subcultured every four to six weeks in liquid medium, under long-day conditions (16 h photoperiod), at 25°C. Viruses can be eliminated by meristem culture at any time during this step. To induce in vitro tuberization, the propagated shoots are transferred to fresh liquid medium that contains 8% sucrose and are cultured in the dark, or under short-day conditions, at 20–22°C. Many microtubers are formed on the lateral shoots within a week, and the tubers continue to grow for another seven to eight weeks. The final fresh weight of the microtubers is usually between 0.2–1.0 g. Recycling smaller microtubers back into propagation of shoots is a preferable option for mass production.[7] Since somaclonal mutation scarcely occurs during these steps, this method enables long-term conservation of disease-free germplasm.[8] The in vitro layering system is also applicable to the conservation of potato viruses. For in vitro tuberization in other plants such as yam (Dioscorea spp) and Jerusalem artichoke (Helianthus tuberosus), a similar method can be employed.

**MICROTUBERS AS SEED TUBERS**

The degree of periderm (skin) development affects the storability of microtubers. Greening of microtubers by light irradiation improves the storability. Microtubers retain their viability for three years under low temperature and high relative humidity storage conditions. Each microtuber produces a single shoot when planted in the field. Early growth of the plant is much slower than that from true tubers, but the plant produces many branches and grows vigorously thereafter. Interestingly, the plant’s final yield of tubers is comparable to that of the plant grown from a true tuber.

**CONCLUSION**

Besides practical use for production of disease-free seed tubers, the in vitro tuberization system is applicable to experimental tools for various basic studies, such as studies on the mechanism of tuberization, carbohydrate metabolism, starch synthesis, and the transformation of plastids (from amyloplasts to chloroplasts). Furthermore, Agrobacterium-mediated gene transformation is easily carried out using this system.[9] Several attempts have been made to improve protein quality and to introduce foreign carbohydrate in tubers. Perhaps in the near future, this method will be applied to produce various useful seed tubers for molecular farming.

INTRODUCTION

Insects comprise more than half of all living macroscopic organisms, and about half of all insects feed on plants. Plant-feeding as a lifestyle is, however, found in only 8 of the 30 insect orders—Coleoptera (beetles), Diptera (flies), Hemiptera (sucking bugs), Hymenoptera (sawflies, wasps, ants, and bees), Lepidoptera (butterflies and moths), Orthoptera (grasshoppers, katydids, and crickets), Phasmida (stick and leaf insects) and Thysanoptera (thrips). Like all other animals, plant-feeding insects eat to acquire the nutrients necessary for growth, reproduction, and general maintenance, and while the qualitative nutritional requirements of all insects are generally quite similar, plant-feeding insects do have some special requirements. An additional issue for plant-feeders is that the nutrient content of plants and plant parts are considerably variable. In some instances, plant-feeding insects have developed mutualistic relationships with microorganisms, which has allowed them to feed on plants, or plant tissues, that lack or contain low levels of essential nutrients.

INSECT NUTRITIONAL REQUIREMENTS

Plant-feeding insects, like other insects and animals, have the ability to biosynthesize some nutrients, although most of the nutrients they need are provided by their host-plants. Nutrients that cannot be synthesized endogenously are classified as being essential, while those that can be produced by using other dietary components are termed non-essential. Much of our understanding of nutrition in plant-feeding insects comes from rearing studies using artificial foods. The most common approach is to omit a specific nutrient from the diet and then measure the effect of this deletion on insect growth and/or reproduction. Once essential nutrients have been identified, the effect of replacing these nutrients with analogs can be measured. Finally, radiolabeled precursors can be used to determine which nutrients are generated endogenously.

AMINO ACIDS

Amino acids, the building blocks of protein, are often considered the most limiting nutrients for plant-feeding insects. There are 20 amino acids that are regularly found in plant proteins, and of these 10 are considered essential (Table 1). Plant-feeding insects use amino acids to build proteins, which can be used for structural purposes, as enzymes, for transport and storage, or as receptor molecules. Individual amino acids also serve important physiological functions. For example, tyrosine is essential for hardening of the cuticle, tryptophan is used in the synthesis of visual screening pigments, glutamate operates as a neurotransmitter, and for some plant-feeding insects proline is an important energy source.

Plant proteins are the dominant source of amino acids, although plants also contain a small pool of free amino acids (usually about 5% of the total). An individual plant will contain a range of different proteins, but the value of any particular protein varies depending on its digestibility and amino acid content, particularly the number and balance of essential amino acids. Ribulose bisphosphate carboxylase is likely to be a particularly important dietary protein because it makes up about 50% of the soluble protein in young leaves.

Protein composition and quality also vary between and within plant species as a result of genetic and environmental factors, as well as within an individual plant as a result of differences in leaf age (e.g., protein content is usually high in young leaves but tends to be lower in old leaves) or plant part (e.g., nitrogen concentration is lowest in xylem and phloem but highest in flower buds and seeds). In general, the absence of any single essential amino acid from the diet prevents growth, and in some instances non-essential amino acids (e.g., proline for the silkworm, Bombbyx) may be required. Even though some amino acids are non-essential, optimal growth usually only occurs when there is a good mixture of non-essential amino acids in the diet.

CARBOHYDRATES

Carbohydrates, which contain the elements carbon, hydrogen, and oxygen in a 1:2:1 ratio, respectively, are the major source of metabolic energy for plant-feeding insects. Carbohydrates are generally split into two groups: sugars (e.g., glucose, fructose, and sucrose) and non-sugars (e.g., starch, dextrin, and cellulose).
The ability of a plant-feeding insect to use a particular carbohydrate depends upon the type of digestive enzymes present in the salivary glands and midgut. Most plant-feeding insects can use sugars, starch, and dextrin, but not cellulose.

Strictly speaking, carbohydrates are not essential nutrients because insects can convert fats and amino acids to carbohydrates via gluconeogenesis. Nonetheless, carbohydrates are considered important, and growth is enhanced when they are provided in the diet. For example, the desert locust, *Schistocerca*, grows best on a diet containing 20% digestible carbohydrates, while the flour beetle, *Tenebrio*, exhibits optimal growth on diets containing 70% carbohydrate. *Tenebrio* fails to develop, however, if the carbohydrate concentrations drop below 40%.

**LIPIDS, VITAMINS, AND MINERALS**

Lipids are found in both plants and animals, where they operate as electron carriers, substrate carriers in enzymatic reactions, components of biological membranes, and sources and stores of energy, and their common property is insolubility in water. Sterols, fatty acids, fat-soluble vitamins, and carotenoids are examples of lipids that are either essential or considered important for plant-feeding insects.

Sterols serve as structural components in cellular membranes and as precursors for steroid hormones (e.g., molting hormone), and are essential nutrients for all insects, in fact all arthropods. Cholesterol (Fig. 1) tends to be the dominant tissue sterol found in insects. Plants, however, rarely contain cholesterol at appreciable levels. The arrows on the four plant sterols indicate structural differences from cholesterol. Of the four plant sterols shown, only sitosterol supports normal growth and development in grasshoppers.

Table 1 Essential and non-essential amino acids for plant-feeding insects. Amino acids that cannot be synthesized by insects are called essential, and these must be obtained from the diet or generated from non-essential amino acids by endosymbionts.

sitosterol being the most common; so plant-feeding insects produce cholesterol by metabolizing the sterols found in their host-plants. Some plant-feeding insects, however, have strict limitations on which plant sterols can be metabolized to cholesterol. Grasshoppers, for example, cannot use sterols with double bonds in certain positions (Fig. 1). Some plant-feeding insects, such as the cactus fly, *Drosophila pachea*, can only use the phytosterols found in the plants on which they specialize.

Most plant-feeding insects also have a dietary requirement for polyunsaturated fatty acids. Generally plant-feeding insects grow well when linoleic or linolenic acid is present in the diet (Fig. 2). The effect of omitting fatty acids from the diet varies from species to species. For example, in the Lepidoptera and Hymenoptera, adults fail to develop properly if linolenic acid is omitted from their larval diet, although this does not appear to be the case for the caterpillar *Heliotis subflexa*. Fatty acids also seem to play a role in...
reproduction because some beetles suffer reduced fecundity and produce slow growing larvae when it is omitted from the diet. The Diptera, with the exception of mosquitoes, do not seem to require polyunsaturated fatty acids.[1]

Vitamins are organic compounds, and plant-feeding insects, like other animals, need them in small amounts. Typically, vitamins are split into two groups based on their solubility in water. The B vitamins, including thiamine, riboflavin, nicotinic acid, pyridoxine, pantothenic acid, folic acid, and biotin, are water soluble. Primarily, they function as cofactors of the enzymes catalyzing metabolic transformations, but they also serve additional roles (e.g., biotin is part of the enzyme pyruvate carboxylase, and folic acid is necessary for nucleic acid biosynthesis).[3] Myo-inositol and choline are components of some phospholipids and are usually required in larger quantities than vitamins. Choline can be produced from methionine, though, so the amount of choline a plant-feeding insect needs will vary depending on the levels of methionine in the diet.[1] Ascorbic acid, which is also known as vitamin C, is required by most plant-feeding insects.

Plant-feeding insects also require two fat-soluble vitamins. The first of these, β-carotene (provitamin A), is a functional component of visual pigments and is involved in the normal pigmentation of plant-feeding insects. It is, however, produced only by plants and microorganisms, and when carotenoids are absent from the diet, insects often appear rather drab and dull, and melanization is reduced.[1] Vitamin E (α-tocopherol) is the other lipid-soluble vitamin needed by most plant-feeding insects. Its presence boosts fecundity, while its absence negatively affects sperm production.[1]

Mineral elements are found in most plant-feeding insects because they are constituents of plants. However, sodium, potassium, calcium, magnesium, chloride, and phosphate are considered essential because they each play an important role in metabolic processes. As with other animals, plant-feeding insects require iron because it is the central element in cytochromes.[1] Zinc and manganese are also required because they play a part in hardening the cuticle of mandibles.[3]

**NUTRIENT POOR FOODS AND ENDOSYMBIONS**

While most plant-feeding insects eat leaves, those in the order Hemiptera have specialized mouthparts that enable them to feed from individual plant cells. For example, some treehoppers (Membracidae) feed from leaf mesophyll, aphids (Aphididae) and planthoppers (Fulgoridae) feed on phloem, and spittlebugs (Cercopidae) feed on xylem. Some plant-feeding insects have also become specialists on wood (e.g., beetles in the family Bostrycidae), while others specialize on detritus (e.g., crickets). Generally speaking, sap, wood, and detritus are not particularly nutritious, so insects feeding on these substrates use endosymbionts, which reside in the alimentary canal and/or intracellularly.
to overcome nutritional deficits.[7] The majority of the endosymbionts in plant-feeding insects are bacteria, although yeast is found in planthoppers and in some wood-boring beetles.[1,7] The endosymbionts of aphids and wood-boring beetles produce essential amino acids from non-essential amino acids, while the endosymbionts of wood-feeding insects digest and metabolize cellulose. Endosymbionts, particularly yeast, may also supply sterols.[3]

CONCLUSIONS

Much of the success of insects as a group has been attributed to their ability to feed on a wide range of foods, and this certainly seems the case for plant-feeding insects because they are found on every plant and virtually every plant part (leaves, stems, flowers, roots, vascular tissues, etc.). Compared to their predaceous relatives, however, the food of plant-feeding insects is nutritionally poor. For example, it has a much lower protein/carbohydrate ratio and is generally lower in sodium. Additionally, many plants contain defensive compounds that are toxic or interfere with digestion.[2] Nonetheless, plant-feeding insects are quite adept at regulating the intake of important nutrients,[8] and they employ a range of pre- and post-ingestive mechanisms to reduce the intake of harmful chemicals and their toxicity, respectively.[2,8] Nutrient regulation is a critical component in determining the individual success of any insect, including economically important pest species, and a more comprehensive understanding of insect nutrition might lead to the development of novel control methods that exploit insect nutritional requirements. Such an approach would be advantageous because it would be target specific and environmentally friendly.

INTRODUCTION

Interactions between insects and other pests can be divided into two broad categories (Fig. 1). The first of these comprises interactions whereby insect pests have an effect on other organisms. These may be beneficial (e.g., pollination) or detrimental (e.g., disease transmission) to the organism concerned. The other major class of interaction involves impacts of other organisms on insect pests. Similarly, these interactions may harm the insect (e.g., predation, parasitism, and pathogenesis) or provide some kind of benefit (e.g., gut symbiosis).

INSECT PEST IMPACTS ON OTHER ORGANISMS

Pest interactions with plant pathogens are of huge economic importance, as many insects are vectors of plant diseases. Although insect vectored diseases are inimical to host plants, resulting in cosmetic damage and yield loss, the insect vectors are highly beneficial to the virus itself. For many viruses, insect vectors are the sole means of transmission, making them integral to the persistence of the virus. The potato-colonizing aphid Macrosiphum euphorbiae (Thomas) (Hemiptera: Aphididae) is responsible for transmission of the virus responsible for potato leaf roll disease (e.g., Ref.[1]). This is a persistent virus, as an aphid individual will remain infective for the duration of its life as a result of viral circulation within the vector. In other cases, for example, potato virus Y, the virus is nonpersistent and transmission will result immediately after feeding begins on a new host plant.

Nonviral pathogens such as phytoplasm are also transmitted by insects. For example, the plant-pathogenic chrysanthemum yellows phytoplasm infects a variety of dicotyledonous plants, causing stunting and phloem hyperplasia, and is transmitted by several species of leafhoppers in the family Cicadellidae. Similarly, European stone fruit yellows phytoplasm is transmitted in a persistent manner by the psyllid Cacopsylla pruni Scopoli (Homoptera: Psyllidae).

Multispecies interactions involving insect pests, weeds, and pathogens are also known. Lettuce necrotic yellows rhabdovirus is transmitted from sow thistle Sonchus spp., which is an alternative host of the virus as well as the aphid vector Hyperomyzus lactucae (L.) (Homoptera: Aphididae).

Insects can also indirectly lead to the spread of plant diseases by producing substances that favor survival of fungal pathogens. For example, honeydew produced by aphids can facilitate growth of fungal diseases such as sooty molds that inhibit growth of the host plant by blocking photosynthesis, and cause damage to fruit. Again, the insects in this example are beneficial to a species of pathogen, but harmful to the host plant.

Insects may, however, act in a way that is beneficial to plants. For example, milkweed Asclepias syriaca (Gentianales) is pollinated by a pest insect, the European skipper Thymelicus lineola (Ochsenheimer) (Lepidoptera: Hesperiidae). In this case, the European skipper would presumably derive some type of nutritional benefit in terms of nectar or pollen.

THE IMPACT OF OTHER ORGANISMS ON INSECTS

The impact of weeds on insect pests is of major ecological and economic importance. Pests may use weeds facultatively as an alternative host as in the case of the mite, Halotydeus destructor (Tucker) (Acarina: Penthaleidae), which will reproduce on capeweed.
Arctotheca calendula (L.) as well as damage desirable species within pastures. Weeds may also constitute alternative hosts that are essential for local survival of insect pest populations. For example, lightbrown apple moth *Epiphyas postvittana* (Walker) (Lepidoptera: Tortricidae) uses broadleaved weed species in the floor of vineyards when the leaves and fruits are absent from the vines during winter months.

In some cases, a weed may provide a specific resource that is otherwise limiting within a crop habitat. In the case of lepidopterans, for example, noncrop vegetation can provide nectar to adults and exacerbate larval damage to the nearby crop. Weeds can, however, benefit pest management by making crop plants less apparent against the soil background. This type of effect is especially well known for aphids, which are unlikely to land on bare soil, but may land on green plant surfaces even if they are not a suitable host. Such “resource concentration” effects are widely acknowledged to be an important explanation for the common observation that severity of pest damage is lessened in polycultures of crops containing weeds.

Weeds may influence pests indirectly via higher trophic levels. There are many cases of weeds providing resources for the natural enemies of pests: foods (e.g., nectar, pollen), populations of alternative hosts/prey, or moderated microclimate. In some instances, however, such resources may benefit the fourth trophic level (parasites or predators of natural enemies).

Entomopathogenic fungi, viruses, nematodes, and bacteria can all cause considerable harm to insects, and consequently, many of these organisms are used in biological control. These pathogens can directly reduce pest populations; however, if they infect natural enemies of the pest, they may indirectly lead to an increase in pest numbers. Although entomopathogenic fungi show promise as a potential alternative to insecticides, care must be taken, as metabolites secreted by these organisms may be toxic to humans. Nonpest insects may also act as vectors for the transmission of fungi, such that an insect natural enemy may reduce pest densities directly through predation/parasitism, and indirectly via fungus transmission.

![Image](Fig. 1) Summary of major interactions between insects and other pests (weeds, pathogens, and nematodes) with arrows depicting the direction of benefits. See text for explanation.
Interactions involving viruses can also be a major cause of insect pest mortality. For example, the single-embedded nuclear polyhedrosis virus of *Trichoplusia ni* (Hubner) (Lepidoptera: Noctuidae) can be introduced to cabbage seedlings at the time of transplanting, and results in 95–97% mortality of Lepidoptera larvae, compared with 4.5% in untreated plots. A variety of baculoviruses are also used for control of Lepidoptera and other insect pests.[7]

Entomopathogenic nematodes are parasites of many lepidopteran, dipteran, and coleopteran pests of commercial crops. Many nematodes have symbiotic relationships with bacteria such that the bacterium (e.g., Photorhabdus) is introduced into the insect via the nematode, then secretes chemicals that kill the insect and converts its tissues into suitable food for the bacteria and nematode.[9] This mutualism and the ease with which nematodes may be cultured make them very suitable as biological control agents in the future.

A number of species of bacteria infect insect pests. One notable example is Bacillus thuringiensis (Bt), which can be cultured and sprayed across a crop in a similar manner to insecticides. An endotoxin of this species is lethal to pest Lepidoptera larvae, and a gene for its production has been used in a variety of transgenic crops.[10]

Despite the numerous instances described above where other pest species have negative effects on insects, interactions with other organisms may also be beneficial to the insect. Many pest insects have mutualistic relationships with gut microbes that facilitate digestion. For example, the gut symbionts Buchnera spp. Munson et al. (a type of gamma-Proteobacterium) interact positively with aphid digestion, thereby producing a benefit for both species.[11]

An interaction where plants may have potentially beneficial impacts on insects involves production of sex pheromones. Many insects require host-plant chemicals as “building blocks” for pheromone synthesis, and the host plant can therefore have a marked influence on sex-pheromone behavior of phytophagous insects.[12]

**CONCLUSIONS**

Insects interact with pests from other phyla in a variety of ways. Many pathogens have evolutionary strategies that are so intimately tied to those of their insect vectors that transmission in their absence is impossible. These insect/pathogen interactions have received considerable attention, as they are highly detrimental to agriculture. Virus transmission is responsible for a large proportion of the economic damage caused by aphids, and nonviral (e.g., bacterial) pathogens can destroy entire crops. However, interactions with pathogens may also be harmful to insects, and are frequently exploited in biological control. A number of entomopathogenic organisms are readily available commercially and can be applied to crops as a living insecticide.

Therefore, the interactions involving insects and other pests outlined above underlie a variety of agricultural problems, yet they also provide a variety of potential solutions. Examination of these interactions may lead to further improvements in biological or cultural pest control, and may simultaneously expose complex symbioses or multitrophic level interactions.

Insect Life History Strategies: Development and Growth

Jeffrey C. Miller
Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

The growth and survival of individuals, family units, and populations perpetuate the species. Adaptations to specific modes of growth and survival lead to the evolution of life history traits. Furthermore, combinations of life history traits involving physiological, morphological, behavioral, and ecological characteristics result in suites of adaptive tactics providing for the expression of certain features that may occur in coincidence or opposition with other features. Combinations and tradeoffs in tactics used to achieve growth and survival are repeated to some degree among species that capitalize on essential resources exhibiting similar attributes regarding spatial and temporal characteristics. For instance, many species capable of rapid colonization of ephemeral habitats exhibit short generation times and relatively high reproductive potential. Such traits exhibited in combination with other traits, such as weak interspecific competitive abilities, provide an adaptive suite of traits generally referred to as life history strategies. The life history characteristics that in sum create the suite of traits involved in life history strategies can be considered in at least eleven component areas: type of metamorphosis, location of life stages, acquisition of food resources, developmental rates, phenology, reproductive potential, dispersal and colonization, competitive behavior, defensive mechanisms, living in extreme environments, and group living and domiciles. Each of these components of life history strategies will be discussed in the context of adaptive suites and tradeoffs in risks and benefits relating to growth and survival.

METAMORPHOSIS

Three principle processes occur in the developmental pathway from the egg, to the immature stage, to adulthood. The most primitive process is ametabolous development. This process involves three life stages: egg, immature, and adult, where sequential molts of immature individuals (instars) do not result in an appearance or ecology that differs to any significant degree from that of the adult, and adults that are reproductively mature may continue to molt. The primitively wingless insects, such as, silverfish, firebrats, and jumping bristletails are some of the more notable groups characterized by ametabolous development. In contrast, the hemimetabolous (including paurometabolous) insects also develop through three life stages, but the immature stages (nymphs or naiads) are distinguished by external wing buds, no pupal stage, and adults that are reproductively mature and do not continue to molt. Fully developed wings are present following the molt from the final instar to the adult. Typically, the ecology of immatures and adults that exhibit hemimetabolous development is very similar. Hemimetabolous development is characteristic of many insect groups exhibiting a diverse array of habits. For instance, aquatic insects such as dragonflies, damselflies, mayflies, and stoneflies. Also, numerous terrestrial plant-chewing and plant-sucking insects exhibit hemimetabolous development, such as grasshoppers, earwigs, walking sticks, true bugs, bark lice, aphids, whiteflies, mealybugs, and scales. The holometabolous insects develop through four distinct life stages: egg, larva, pupa, and adult. The immature stages, unlike in ametabolous or hemimetabolous development, exhibit a morphology and ecology typically very different from the adult stage. The transition from immature to adult occurs most dramatically in the pupal stage when the larva with internal wingbuds transforms into the reproductively mature adult with fully developed external wings. Holometabolous development is characteristic of the groups comprising a majority of insect biodiversity, such as beetles, butterflies, moths, lacewings, caddisflies, true flies, sawflies, wasps, bees, and ants.

Regardless of which developmental process is followed by an insect species, the major function in the immature stage is acquisition of food for growth, while the major function of the adult stage is reproduction and dispersal. Uncommonly, the immature stages are the primary dispersal agents and select life history tactics are associated with this condition, as discussed under colonization. The fact that most insect species exhibit holometabolous development suggests that holometabolous facilitates resource partitioning between immatures and adults, which reduces competition between the life stages and in turn enhances the exploitation of specialized niches, resulting in higher levels of speciation.
LOCATION OF LIFE STAGES

The sites for development of eggs, immatures, the pupa, and adults may involve many types of environments and microhabitats. For instance, herbivorous insects may occur on the surfaces of plants or within plant organs. The location of the various life stages is relevant to life history strategies because specialized adaptations are necessary to mediate physical and biological conditions encountered in the variety of microhabitats throughout the environment. Adaptations may be needed for defense against soil microbes, extracting nitrogen from a low nitrogen source like plant sap, or tolerance of temperature extremes. The life history of a typical geometry moth illustrates the complexity of a holometabolous life cycle where each of the four life stages occurs in a different microenvironment: Eggs are placed on the plant; caterpillars feed on leaves; pupation occurs in the soil; and the adult is free-flying and feeds on nectar or does not feed at all. In general, immatures of herbivorous insects function in the role of seed-, root-, crown-, or stem-borers, leaf-miners, leaf-chewers, or phloem- or xylem-feeders. The type of food consumed may be a specific resource or a generalized set of resources. An insect herbivore that is a specialist feeder may be either a taxonomic specialist, which means the insect feeds on only one plant species or a few species within the same genus, or a plant part specialist, which means the insect feeds only on seeds or roots, etc. In extreme cases, a generalist insect herbivore might feed on a hundred or more plant species across several plant families. The acquisition of suitable food resources and the condition of being a food specialist or generalist can involve many types of life history traits regarding morphology, physiology, and behavior (Fig. 1).

FOOD RESOURCES

Numerous specialized morphological adaptations and numerous life history traits are associated with the behavioral and physiological adaptations involved in avoiding starvation, locating food, and food acceptability. Among the tactics employed to mitigate starvation are cannibalism, oosorption (females are able to reabsorb nutrients from eggs still in the reproductive tract), protein reclamation from muscle degeneration, and development through an extra (supernumary) molt. One of the dominant themes regarding food resources is the condition of specialist and generalist feeding habits and vegetation as apparent and unapparent plants. Specialist feeders have a low probability of randomly finding food; therefore, they must possess traits that place them in the proper habitat at the proper time for exploitation of their respective food resources. For specialists the proper habitat can be discovered by detecting certain cues such as unique form and color, or unique and often toxic chemicals characteristic of apparent plants. In addition to serving as cues in the process of host plant location, certain otherwise toxic plant chemicals may serve as phagostimulants and as a protein source for nutrition and defense mechanisms. On the other hand, generalist feeders may have a higher probability of encountering a seemingly random but acceptable food resource, but do not derive notable chemically based defensive properties from the unapparent plants, because the foliage is devoid of acutely toxic compounds. The timing of life stages to coincide with the availability of required food resources is an issue of phenology and is discussed after developmental rates.

DEVELOPMENTAL RATES

The rate of development depends on three main factors: temperature, nutrition, and genetics. Temperature is critical to insect development and is the focus of mathematical models capable of predicting insect developmental rates. The temperature-dependent growth models require information regarding two key variables in insect life history traits: 1) temperature thresholds (upper and lower) for development and 2) heat-unit requirements above the lower developmental threshold needed to complete development of each life stage. Typically, insects inhabiting temperate latitudes exhibit a lower developmental threshold in the range of 5–15°C. One of
the tradeoff considerations regarding temperature-dependent growth and life history traits is that a low lower developmental threshold might allow for a rapid accumulation of heat-units and, therefore, rapid growth rates. However, a low lower developmental threshold may also compromise tolerance regarding the upper developmental threshold, which, if exceeded, will result in death due to an intolerance of heat. Likewise, a higher value for the lower developmental threshold may confer a cold intolerance and a slower rate of heat-unit accumulation that could result in a slower growth rate. As with other life history traits, the genetically based developmental thresholds are, to one degree or another, characteristic of family units, populations, and species. The ability of an insect to thermoregulate, increase body temperature through rapid muscle contraction or basking in the sun, involves life history traits that allow certain species to defy environmental temperatures that otherwise would preclude an activity such as feeding or flight. Because temperature is a dominant factor in determining growth rates, it is also the case that temperature is influential in determining the seasonal occurrence of life stages and therefore the phenology of various events that must occur in synchrony, such as the timing of egg hatch with the occurrence of bud break and leaf maturation.

PHENOLOGY

Three aspects of phenology are particularly relevant to life history strategies: 1) diapause, 2) overwintering, and 3) voltinism. The onset of diapause and overwintering are often coincidental in nature. That is, particularly among temperate zone insects, overwintering life stages will be in a state of diapause that was triggered in part by declining photoperiod in the autumn. The gradual conclusion of the diapause condition is triggered by a cold period followed by warming above the lower developmental threshold. A combination of factors, including developmental threshold values, heat-unit requirements, diapause conditions, and the temperatures characteristic of the habitat, will determine how many generations an insect population may exhibit within one year. Univoltine species cycle through only one generation per year and typically exhibit relatively narrow variance in the seasonal occurrence of the various life stages, whereas, multivoltine populations may cycle through many generations per year and exhibit a wide variance in the presence of various life stages and have overlapping generations. Among other considerations, a consequence of voltinism in combination with the length of time necessary to complete a generation is the effect on potential reproductive potential expressed by the population or species.

INTRODUCTION

Insect herbivore life history traits related to development and growth are integral to understanding the life history traits regarding reproduction and survival. In fact, the relationships cannot fully be appreciated unless the adaptive nature of each life history trait is considered in the context of natural selection and its affects and effects concerning variation across temporal and spatial scales, predictable and unpredictable aspects in environmental constancy and heterogeneity, variation in genetics, the fitness value of a given combination of alleles, and the high diversity of combinations in life history traits. This article on insect life history strategies concentrates on adaptations regarding reproductive potential, dispersal and colonization, competitive behavior, defensive mechanisms, living in extreme environments, and group living and domiciles.

REPRODUCTIVE POTENTIAL

The total number of offspring, the timing of delivery of offspring, and sex ratio are central themes in life history strategy analysis.[1–3] In fact, the concept of r- and K-selection[4] is predicated on the dynamics of birth and death rates that on balance represent the reproductive capacity of a given population or, in a very general application, the species. Species that exhibit a high fecundity (total egg production per female) may also exhibit short generation times and may be multivoltine. The annualized reproductive capacity of such a species is extremely high. On the other hand, the rates of mortality in such a species may also be extremely high, resulting in highly volatile population densities. Other life history traits that may be associated with highly fecund species are rapid colonizing ability (discussed shortly), generalist food requirements, intense intraspecific competition for limited resources, and inferior interspecific competitive ability.[5,6] Conversely, species exhibiting lower levels of reproductive potential may be slower to colonize newly available habitats, but once they do they may retain their presence by being more specialized in food requirements and superior interspecific competitors (Fig. 1).

Many insect species may control the sex ratio of their offspring through various mechanisms where the female can regulate the fertilization of her eggs with sperm stored in a special pouch called the spermatheca. One sex determination mechanism is arrhenotoky, also known as haplo-diploidy, where haploid offspring are males and diploid (fertilized eggs) offspring are females. Some species of weevils and all of the Hymenoptera are arrhenotokous. The ratio of female to male offspring has the direct consequence of altering the dynamics of population growth rates. Some species do not possess males during any part of their life cycle or only during certain generations in a multivoltine life cycle. For instance, aphids develop through a sexual generation from the fall through winter and into the spring; however, in late spring and during the summer, many species will develop through numerous parthenogenetic generations that lack males. In the case of aphids, other life history traits are associated with the alternation of sexual generations, such as shifts in specific host plant affinities between generations. During the summer, asexually produced females are wingless, the parthenogenetic females give birth to live young, and summer populations typically occur in large aggregations on plants. Each of the individual features illustrated by the complex aphid life cycle contributes to an extremely high reproductive potential due to a mix of life traits that in combination contribute to rapid population growth. On the other hand, aphid life history strategies are associated with considerable risk regarding mortality due to predation. A diverse complex of predators, parasitoids, and diseases, each with their own life history strategies, may at times counterbalance the high reproductive potential inherent in aphid populations and thereby regulate aphid numbers to very low population densities. An effective defense against natural enemies is dispersal, an action allowing escape and affecting survival in other ways as well.

DISPERAL AND COLONIZATION

The movement of individuals is critical for the exchange of genes among and between populations, which in turn is essential for adaptation to changing environments and for placing an individual in a certain life stage into a suitable
Long distance movement, including migration, in insects is a mode of active dispersal generally controlled by flight. Migrations are not a prevalent feature in life history strategies of herbivorous insects but are well known in a few species, such as the monarch butterfly, the milkweed bug, and some species of noctuid moths. However, aerial passive dispersal over distances measured in kilometers is a relatively common behavior. Aerial passive dispersal is strongly influenced by wind currents, thus the insect must be buoyant and may be incapable of flight. For instance, certain Lepidoptera disperse in the larval stage. The caterpillars typically are hairy or spin silk for buoyancy and have generalist feeding requirements, and the females are flightless but highly fecund, whereas the male is winged and capable of flight. Flightlessness is an obvious condition of adult insects exhibiting aptery and brachyptery with the activity of dispersal dependent on a passive mode; however, the feature of flightlessness is not necessarily a fixed trait. Species may possess various states of wingedness that are expressed through a suite of polymorphic conditions that in some cases are sexually determined. The expression of sexually dimorphic traits, polymorphic features, differences in colonizing abilities, and reproductive potential also interrelate with considerations of competitive behavior and defensive mechanisms.

**COMPETITIVE BEHAVIOR**

Insect herbivores compete within and among species for limited, essential resources. Therefore, life history traits exist that either enhance the competitive edge of one species over another or provide a means for one species to minimize competition for limited, essential resources such as mates, oviposition sites, food, and shelter. Two of the primary tactics employed by insects to gain a competitive advantage are 1) the use of chemical markers and 2) the expression of aggressive behavior. Numerous insect species mark parts of the habitat with pheromones. An example of habitat marking is the placement of a pheromone with a newly deposited egg, which has the effect of deterring oviposition by other females of the same species at or near the same place. Pheromones are also prevalent in mating behavior, trail maintenance, colony integrity, and warning signals. Interestingly, the pheromones that may alleviate intraspecific or interspecific competition for food among herbivorous species may serve as a cue in aiding natural enemies of the herbivores in prey location. The expression of aggressive behavior is manifested in life history traits such as cannibalism and various degrees of combat, from pushing and shoving to biting and stinging to the death of one or both of the combatants. Many herbivorous insects are cannibalistic, that is, they will kill and in some cases consume individuals of their own species. Cannibalism is most commonly encountered in species exhibiting a solitary lifestyle. For instance, caterpillars are immature Lepidoptera, a group that is virtually herbivorous in nature, and yet individual caterpillars will fight with and consume other caterpillars of the same species, or different species, when they encounter one another on their host plant. Aggressive behavior also provides an important component of defensive mechanisms.

**DEFENSIVE MECHANISMS**

Numerous life history traits are involved in defense mechanisms, such as, as previously mentioned, flight for escape, mimicry for appearing to be another species that possesses a threatening or toxic defense, aposematic coloration for warning predators of toxic compounds, crypsis for camouflage and for hiding out in the open, startle behavior for scaring off a potential attacker, feigning for appearing to be dead, expulsion of liquids for repelling an attacker, spines and poison glands, alarm pheromones, domicile construction, and guarding behaviors for protection of progeny or a colony. Each of these features, and many more, may be found occurring in combination with one another in an insect species. In general, the adaptive nature of any particular suite of defensive mechanisms is dependent upon the intensity of the selective pressure exerted by a given mortality factor. For instance, a species of beetle, such as the Colorado potato beetle, whose larva is a specialist feeder on the foliage of potato, which is a toxic plant, may gain protection from enemies by sequestering the plant allelochemicals that otherwise confer protection to the plant against generalist herbivores. The ability to sequester toxic compounds will have limits and may be
genetically determined and, thus, subject to variability within the population, as in monarch butterflies where certain individuals lack the cardiac glycosides responsible for the aposematic coloration of the adult. If the ability to sequester the toxic compound has an energetic cost, perhaps measured relative to reproductive potential, then individuals that are not capable of sequestering the toxic compounds are at risk, but they might gain a benefit if predation is not a primary mortality factor. Other defensive mechanisms involve mimicry and crypsis, which are expressed through morphological characters and coloration, traits that can vary based on selective pressures and genetically based polymorphisms. As mortality due to predation changes in time and space within the environment so will the gene frequency regulating the expression of each particular state of the polymorphism. Each genotype within the polymorphic suite of traits can exhibit a different fitness value depending on the presence and absence of predators. Thus, the tradeoffs in benefits and risks can have the consequence of changing the trend of directional selection. The principle of tradeoffs in benefits and risks in life history strategies is also well illustrated by considering adaptations to extreme environments.

EXTREME ENVIRONMENTS

Specialized morphological features and character reduction are two common types of adaptations to extreme environments. Some examples of these are a lack of color in certain species living in habitats devoid of light, such as caves; a lack of sight, as in certain soil-dwelling blind ground beetles; extremely dorso-ventrally flattened bodies typical of many leaf-mining caterpillars; and exaggerated features, such as the enlarged antennae associated with cave-dwelling crickets or the fossorial legs present in the soil-dwelling nymphs of cicadas. Similarly, insects in arid environments will exhibit specialized traits such as an extremely waxy cuticle, high numbers of Malphigian tubules, or physiological means for excreting uric acid instead of ammonia. Each one of these traits provides a selective advantage due to benefits regarding water conservation. Overall, growth and survival in extreme environments will depend on a combination of life history traits involving other physiological mechanisms and behavioral activities regarding the timing of dispersal to avoid harsh environmental conditions, phenology of life stages and diapause or aestivation, reproductive potential to compensate for high mortality, food resource requirements, and developmental biology, which determines growth rates and voltinism. One additional feature in life history strategies relates to the mitigation of adaptations to extreme environments through the behavior of group living and the activity of domicile construction.

GROUP LIVING AND DOMICILES

Insects may occur as solitary individuals, in groups consisting of a few to hundreds of individuals, or in a family unit consisting of thousands of individuals. Some of the benefits of group living are protection from natural enemies, cooperation for brood care, and in some cases construction of nests, as occurs with social insects such as termites, bees, and ants. However, one of the risks of group living, whether it is as a simple aggregation of aphids on the exterior of a leaf or as a social unit inside a nest, is the supply of adequate food reserves. Among the social insects, the means for gathering and storing large quantities of food involves specialized life history traits including morphological features such as enlarged fore-guts or hindguts, pollen baskets, physiological processes resulting in caste differentiation, behavioral mechanisms such as feeding via trophallaxis, and sanitation. Also, social insects are noted for their communal construction of domiciles; however, living within a domicile is not restricted to the social insects. Numerous species of herbivorous, nonsocial insects live within structures of some sort. For instance, gall-making insects, notably certain beetles, flies, wasps, and aphids, may stimulate their host plant to create a gall that includes a supply of nutritive tissue as well as a place to house the immatures and provide a barrier to guard against the outside environment. Although the benefits of a gall are obvious, one of the risks is that a predator capable of invading the gall space can readily consume its otherwise defenseless prey.

CONCLUSION

The subject of insect life history strategies is a well-studied topic on the basis of empirical data, concepts, and models. Basically, the topic focuses on considerations of variability in the environment, variability in genetics of the organisms responding to the variable environments, and the relative advantages and disadvantages of various combinations of life history traits across spatial and temporal components of the environment.

INTRODUCTION

The development of plants with resistance to insects is a proven method for managing insect pest populations. Many insect-resistant crop varieties have played vital, integral roles in sustainable systems of agricultural production. Resistant varieties are nonpolluting; ecologically, biologically, and socially acceptable; and economically feasible as a means of pest control. In the eighteenth and nineteenth centuries, insect resistant varieties of cereals and fruits were first developed and cultivated in Europe and North America. When the grape phylloxera, *Phylloxera vitifoliae*, destroyed the French wine industry during the late 1880s, resistant rootstocks from the United States were grafted to French scions, and the industry recovered.

TERMINOLOGY

Plant resistance to insects is the sum of the inheritable genetic qualities that result in a plant of one variety or species being less damaged than a susceptible plant lacking these qualities under a similar pressure of herbivory.[1] Resistance is measured on a relative scale, and the degree of resistance is based on comparison to susceptible plants that lack resistance in the same experiment.[2] Variation in insects, test plants, and the environment may affect the expression of resistance, often resulting in pseudoresistance in normally susceptible plants. The effect of each variable should be determined before concluding that a plant is resistant.[3]

Associational plant resistance to insects occurs when mixtures of plant species slow pest insect population development on normally susceptible plants growing in association with resistant plants[4] or plants infected with fungal endophytes that produce alkaloids that kill or delay the development of pest insects.[5] Searches for resistance can be directed at selection for either allopatric resistance (plants evolving in the absence of insect pressure—no previous evolutionary contact) or sympatric resistance (plants evolving in the presence of insect pressure).[6]

FUNCTIONAL CATEGORIES OF RESISTANCE

Painter[7] defined the negative effects on insect biology of chemical and morphological plant defenses in resistant plants as antibiosis. These defenses may be overcome by the expression of virulence genes in an insect pest population after prolonged exposure to high levels of antibiosis. Populations expressing virulence are known as insect biotypes. Many biotypes are parthenogenetic (reproduce asexually) aphid species, or Dipteran and Heteropteran species with high reproductive potentials that infest large cereal (rice and wheat) monocultures. Biotypes have been identified by phenotypic plant reaction for many years, but DNA marker techniques are beginning to be employed for more accurate identification of biotypes.

Resistance is also manifested as antixenosis, where chemical or morphological plant factors result in pest insect selection of alternate host plants.[8] The resistant plant may also be able to withstand or recover from insect damage and yield as much or more biomass than a protected susceptible plant. In this case, resistance is expressed as tolerance to the pest insect. An advantage of tolerance is that although the pest population level is not reduced, an ample food source for pest predators and parasites is provided, and synergizes the beneficial effects of these biological control agents. Frequently, resistant plants exhibit multiple resistance categories.

In addition to enhancing biological control, even moderate levels of resistance combined with insecticides can greatly reduce insecticide use costs and the amount of insecticide residues. This effect has been demonstrated in many different agricultural systems.[9] In some cases, insect-resistant varieties offer producers genetically incorporated insect control for the cost of the seed alone. Insect-resistant varieties provide a substantially greater rate of return on investment than do insecticides. The current global economic value of all insect-resistant crop plants, based on increased crop yields and reduced insecticide use, is approximately $2.7 billion per year[9] (Table 1).
INSECT RESISTANCE TRANSGENES

Two changes occurred in the development of insect-resistant varieties near the end of the twentieth century. First, Agrobacterium transformation systems and biolistic projectile devices were used to transfer genes encoding insecticidal crystal (cry) toxins from the soil bacterium Bacillus thuringiensis (Bt) into crop plants. After ingestion, crystals are solubilized in the alkaline environment of the insect gut, where active toxic fragment(s) are released by insect digestion, bind to specific receptors on the midgut cells of susceptible larvae, and then cause osmotic lysis of those cells, and insect death. Several crop plants have also been transformed with transgenes expressing insect digestive enzyme inhibitors of both plant and insect origin.

Before the development of Bt transformants, numerous studies determined that insects became virulent to the cry toxin gene after prolonged exposure to high doses of Bt, similar to how high doses of conventional pesticide or high levels of conventional gene expression lead to virulence in target insects. One early research study indicated that Bt corn was toxic to the monarch butterfly, Danaus plexippus. Subsequently, the U.S. National Academy of Sciences reviewed a series of several other experiments and concluded that the risk to monarchs from Bt corn is not significant. One Bt corn event grown on a very small U.S. hectarage was shown to be toxic to monarch larvae and is being eliminated from production.

To obtain their maximum longevity, Bt insect-resistant transgenes in corn and cotton are deployed with non-Bt plant refuges that enable the survival of pest moths from susceptible larvae to mate with moths produced from larvae virulent to Bt. Shifting the mortality of larvae heterozygous for virulence from 50% to 95% provides a tenfold delay in time before the development of virulence.\[10\]

Although numerous transgenic crop plants have been developed, only the production and marketing of transgenic corn, cotton, and potato varieties have proceeded in North America and Asia. However, because these are essentially insecticidal plants, their deployment strategy has proven complex, and their production and use have met with strong opposition by environmentalists, primarily in Europe. Estimates are that recommended insecticide use against one insect pest of corn, Ostrinia nubilalis, dropped approximately 30% after the commercialization of Bt corn in North America.

DNA RESISTANCE MARKERS

The second major shift in the development of insect-resistant plants is the adaptation of genotypic screening techniques to identify insect resistance genes. This change involves isolating DNA from resistant and susceptible parents, amplifying complementary DNA with molecular markers from known chromosome locations, separating the DNA amplification products by electrophoresis, and identifying primers that differentially amplify the DNA of resistant and susceptible parents and their progeny in a polymorphic (informative) pattern. DNA markers have several advantages over phenotypic markers. They can be codominant and detect heterozygous patterns of inheritance, where morphological markers behave in a dominant/recessive manner and do not. The allelic variation of DNA markers is greater than for morphological markers. Finally, molecular markers are unaffected by the environmental fluctuations that have been shown to have a significant effect on morphological markers. DNA markers can be used to map resistance genes inherited as dominant traits at single loci, or as quantitative traits, located at multiple loci and linked to several minor genes contributing to insect resistance.

The chromosome location of many constitutive insect resistance genes has been identified in a wide number of crop plants using molecular markers.\[11\] However, the

only insect resistance gene cloned to date is Meu1 from wild tomato, Lycopersicon peruvianum, which confers resistance to the potato aphid, Macrosiphum euphorbiae, and the root knot nematode, Meloidogyne incognita. Meu1 is a member of the nucleotide-binding site and leucine-rich region (NBS–LRR) family of disease and nematode resistance genes.

EXPRESSIONED RESISTANCE GENES

While research on constitutive herbivore resistance genes is only beginning, progress is also being made in the identification of unique mRNA transcripts expressing induced insect resistance genes that are produced by several species of plants. In essence, tissue damage caused by components of insect saliva contacting plant tissues activates an octadecanoid signaling cascade that leads to biosynthesis of signals such as jasmonic acid, salicylic acid, ethylene, and abscisic acid that in turn activate the production of many different types of insect antifeedant compounds. Chewing insects elicit plant responses different from those induced in response to feeding by piercing/sucking insects. In addition, the end result of hypersensitive responses to insect feeding is often the production of enzymes that lead to cell wall thickening in resistant varieties, hindering insect feeding and digestion. In cereal plants, induced disease and nematode resistance gene loci occur in clusters and there is evidence that insect resistance genes occur in a similar manner.

CONCLUSION

Insect-resistant crops play an important role in world sustainable agricultural systems, and will become more prominent as world food needs increase. Resistant varieties have proven to be ecologically and socially acceptable to consumers, and economically feasible for producers. Although there have been many successes in deploying insect-resistant genes in improved varieties, it is not completely clear how plants recognize the attack and feeding by different insects. However, chemical and mechanical stimuli perceived by plants during insect feeding contribute to plant recognition of feeding. Very limited information exists about the molecular aspects of plant response to insects, but a partial understanding is emerging. The continued use and refinement of molecular marker techniques to genotype constitutive and induced insect resistance genes in plants should continue to provide the necessary information to determine the molecular bases of plant genetic defenses against insects.

The use of functional genomics will enable the sequencing of additional insect resistance genes in many plants, and will help develop refined genetic maps of these genes. A more complete understanding of pest resistance genes will reduce the possible development of virulent, resistance-breaking insect biotypes and lead to more rapid development of crop varieties with greater and more diverse levels of insect resistance.

INTRODUCTION

Insects and plants have evolved together for millions of years, and their relationships are both antagonistic and mutualistic. Antagonistic associations arise because the energy trapped in plants during photosynthesis is used by approximately half of the species of insects. Insects of the six largest orders (Orthoptera, Hemiptera, Lepidoptera, Coleoptera, Diptera, and Hymenoptera) derive most or all of their food directly from plants. However, despite extensive herbivory by insects, plants continue to flourish, in part because of defenses that they have evolved against insect attack. As a result, no insect species feeds on all plants, and no plant species is eaten by all insect herbivores. Certain insect species have, however, evolved effective means to overcome plant defenses, and in turn new plant defenses have evolved. Coevolution has also resulted in the development of mutualistic interactions that benefit both plants and insects in diverse ways. This review will outline plant–insect interactions that are beneficial to insects, those that are beneficial to plants, and certain mutualistic interactions.

INTERACTIONS OF BENEFIT TO INSECTS

Feeding

Insects profit by using plants as sources of food. All parts of a plant may be eaten by phytophagous insects: roots, sap, stems, leaves, buds, pollen, nectar, fruits, seeds, and decaying plant tissue. Monophagous insects feed on one or a few plant species, whereas polyphagous insects include a wide range of plants in their diet. Plants provide insect herbivores with nutrients necessary for growth and development, such as water, nitrogen, carbohydrates, amino acids, lipids, minerals, and vitamins. Plants also serve as sources of sterols required for production of hormones.

Plant growth is affected negatively when photosynthetic tissue is eaten, phloem sap is drained, or uptake of water and minerals is affected as a result of feeding by chewing and sucking insects. Chewing insects feed either externally or internally, as borers or miners. Sucking insects imbibe juices and cause weakening and yellowing of plants. These influences result in stunted growth, lowered production of seeds, weakened competitive abilities, or plant death. In addition, damage to flowers, fruits, and seeds directly affects population growth of plants. Further, some insects inject toxins or disease organisms such as viruses during feeding, which can have additional detrimental impacts on host plants. Certain insect species such as leafcutter bees transport pieces of leaves to line their nests, whereas leafcutter ants use parts of leaves as a substrate for growing fungi in their nests.

Several species of phytophagous insects induce the production of abnormal growths called galls in their host plants. Galls are found in buds, leaves, stems, flowers, or roots, and their shapes and locations are often characteristic of the plant and insect species concerned. They provide insects with a rich source of food and protection from predators and the elements.

Oviposition

Plants provide sites for oviposition that enable immatures to commence feeding soon after egg hatch. Egg laying is a critical step in the life cycle of insects, since survival of progeny is highly dependent on recognition of suitable host plants by gravid females. Newly emerged larvae are often limited in their dispersal abilities, and hence host selection is a function of the ovipositing females. Eggs are often attached to plants and may be laid singly or in groups on any plant part. In certain insect orders such as Hemiptera, several species conceal their eggs by insertion into plant tissues.

Additional Benefits

Not all interactions beneficial to insects are detrimental to plants. Plants provide insect herbivores with shelter from natural enemies and the elements, rain and sunlight. Plants can also act as sites for mating.

INTERACTIONS OF BENEFIT TO PLANTS

Despite the great number of phytophagous insect species that exist, plants continue to dominate the landscape. This suggests that plants are a formidable evolutionary barrier...
that many insects are not able to overcome. Plants possess morphological or chemical defenses (discussed below) that enable them to escape insect attack.

**Carnivorous Plants**

Certain plant species use insects to supplement their nutrition. These carnivorous plants are found in nitrogen-poor soils, particularly in acid bogs and heavy volcanic clays, and their root systems are not extensive. Carnivorous plants trap and digest insects. Trapping mechanisms include sticky exudates that entangle insects, such as in sundews; structural modifications, such as the pitcher on pitcher plants; or modified leaves such as those in the Venus flytrap. Trapped insects are digested by enzymes secreted from various glands, and amino acids—the nitrogenous compounds in insects that are beneficial to the plant—are absorbed by special tissues in the plant.

**MUTUALISTIC INTERACTIONS**

Different species or guilds of species that have coevolved to the extent that they benefit each other are considered mutualistic. Mutualistic interactions between insects and plants have evolved on several occasions. Many angiosperms, or flowering plants, are dependent on insects for pollination. More specialized mutualistic interactions have evolved such as those between neotropical species of acacia trees that produce secretions attractive to an aggressive ant species, which in return protects the trees from insect herbivores.

A lesser-known mutualistic interaction that has gained attention in recent years exists between plants and the natural enemies of herbivorous insects. Natural enemies, parasitoids and predators of insect herbivores, cue in on stimuli associated with plants in habitats where their hosts are likely to occur. Predators and parasitoids benefit by reduction of the time spent in searching, whereas plants that provide appropriate cues for attracting natural enemies benefit by the reduction in herbivory. Although undamaged plants attract natural enemies, the influence is enhanced when plants are damaged by herbivores.

**FACTORS AFFECTING INSECT–PLANT INTERACTIONS**

Insect species use a restricted range of taxonomically related plant species. Distinct food preferences are to a large extent attributable to an insect’s ability to identify acceptable host plants on the basis of plant-related traits, amid a multitude of nonhosts. Host location by herbivorous insects is a complex process involving a hierarchy of cues, some acting from a distance and some at close range.

Host plant selection in insects includes host habitat finding, host finding, host recognition and acceptance, and host suitability. Plant-related factors can influence each of these steps. Differential colonization of plant varieties by the same insect species may be due to differences in morphological or chemical traits. Plant traits such as architecture, thickened cell walls, or trichomes (small hairs on plant surfaces) impede surface penetration or herbivore movement, and thereby influence insect herbivores directly. Such traits can benefit herbivorous insects indirectly when they exert negative impacts on predators and parasitoids, thereby providing enemy-free space. As a result, parasitoids and predators are more successful in locating and accessing their hosts or prey on certain plant species than on others. Chemical traits in plants that have negative impacts on insect herbivores include secondary plant metabolites produced by plants. These include alkaloids such as caffeine and nicotine, pyrethrum, tannins, and diverse other compounds that are difficult to handle and hence deter herbivory. Plants also produce compounds that function as protein inhibitors or insect growth regulators, and thereby affect metabolism and development.

Insects and plants have evolved chemical messenger systems involving diverse allelochemicals (Fig. 1). An allelochemical is a chemical involved in an interaction between organisms belonging to different species. When plant compounds evoke a reaction in a receiving herbivorous insect that is favorable to the plant but not the insect, the compound is called an allomone. Allomones include toxic plant compounds mentioned above that serve as defenses against herbivory. In chemically-mediated
interactions where the receiver benefits but not the emitter, the chemical involved in the relationship functions as a kairomone. In plant–insect interactions, examples of kairomones include phytochemicals that attract herbivorous insects to their host plants. When plants produce chemical cues that draw natural enemies to habitats of their hosts, the chemicals involved in the interactions function as synomones, because the emitter and receiver of the chemical both benefit from the interaction.⁹

Plant-related allelochemicals are used extensively by insects for location of appropriate host plants for feeding or oviposition purposes. Typically volatile compounds from plants serve to draw insects from a distance, whereas more stable compounds serve as short range cues for arrestment and ultimate acceptance of the plant. Attraction of an insect to a plant may be due to the presence of specific compounds such as allyl isothiocyanate in cruciferous plants, the presence of specific blends of compounds, or the absence of deterrent compounds.

Some insects are able to overcome the detrimental effects of chemical defenses in plants by detoxification, sequestration, or excretion. In addition, certain species that sequester toxic phytochemicals use these compounds to their advantage in their relationships with conspecifics or members of other species. For example, moths of Utetheisa ornatrix sequester pyrrolizidine alkaloids acquired from their food plants during larval development. The alkaloids are involved in mate selection and are also transferred to eggs, providing protection against predation.¹⁰

FUTURE CHALLENGES

The examples presented here provide some insights into the diversity of interactions between plants and insects. Coevolutionary processes in nature continue to modify these relationships. In addition, human practices bring about further changes in associations between plants and insects. For decades, plant–insect interactions have been exploited in conventional plant breeding programs for development of cultivars that are resistant to attack by insect pests, but little attention has been directed toward impacts on natural enemies. With biotechnology advances, evolutionary changes in plant–insect interactions are likely to be expedited. Evaluation in risk assessment programs of the impacts of genetically modified plants on herbivorous insects and their natural enemies is critical, and it presents a tremendous challenge due to the complexity and diversity of plant–insect interactions.

INTRODUCTION

Vectors are organisms that can introduce a pathogen such as a bacterium or virus into a plant to cause an infection. Insects, mites, and nematode vectors focus the movement of plant pathogens among immobile plants. Many insects or other arthropods may contain plant pathogens but cannot transmit these to plants and thus are not vectors. Some of our most important plant diseases require mobile vectors. Almost all plant viruses and all wall-free, plant pathogenic bacteria known as mollicutes have recognized or suspected vectors. See elsewhere for insect vector transmission of bacterial plant pathogens.

Much research on vector transmission seeks to understand the transmission process so as to explain why only certain kinds of insects or mites can serve as vectors and to identify what factors are required for transmission.[1] Because insecticides applied to kill vectors frequently fail to control the diseases caused by the vector-borne pathogens, a good understanding of the relationships between vectors and the pathogens that they transmit is important.

Vector transmission processes are usually complex, even for the seemingly simple mechanical transfer of plant viruses to plants on the tips of vectors’ stylet-like mouthparts (similar to a hypodermic needle) during feeding. In many other cases, the plant parasites transmitted by insect vectors must multiply and circulate throughout the body of the vector to be transmitted. The most fundamental characteristic by which to classify or categorize vector transmission is that of transmission efficiency (also called vector competence), or how often a vector transmits a pathogen over time or per transmission opportunity. Transmission efficiency can increase or decrease over time after a vector first acquires a pathogen, usually by feeding, but some pathogens are transmitted from a mother vector to her offspring via her eggs or embryos. Generally, vector acquisition of pathogens increases with time spent feeding on infected plant sources of the pathogen. Transmission is called nonpersistent if the rate of transmission drops to near zero within a short time (hours). Nonpersistent transmission of viruses also differs from other types of vector–pathogen relationships in that acquisition generally decreases rather than increases with sustained feeding on infected plants. Semipersistent transmission persists for, at most, a few days after acquisition. Persistent transmission describes situations in which the vector can transmit over many days, in some cases, for weeks or months.

LATENT PERIOD

Vectors that increase their transmission rates over time have a latent period: the time between a vector’s acquisition of the pathogen and its first transmission to plants. Some vectors never transmit a pathogen until days or weeks after they first acquire it. In contrast to these long latent periods, some vectors need no latent period; transmission can occur immediately after acquisition. (See Table 1 for examples.)

The nonpersistent transmission of viruses by aphids illustrates the importance of how vector transmission characteristics contribute to the spread of plant disease and why some control strategies for these viruses differ from those for other aphid-transmitted viruses. Potato virus Y (PVY) and other potyviruses are transmitted by a wide variety of aphids (family Aphididae; Fig. 1) in a nonpersistent manner (relatively low vector specificity). The optimum time for an aphid to acquire PVY is after only a few minutes of feeding. The most convincing experimental evidence points to the tips of the vector stylets (Fig. 2) as the critical region where the nonpersistent nature of the transmission of PVY fits in well with the flight behavior of its aphid vectors to promote virus spread in crops. Alighting aphids typically make a few probes on the first plant on which
they land and then fly short distances to other plants until they settle to feed continuously and reproduce. Because the aphids rapidly lose infectivity, they do not often disperse the virus over long distances. Most virus spread in such cases is from plant to plant within a field, making sanitation to eliminate seed transmission or other ways that introduces virus into a crop a key control method.[4] The aphid vectors’ rapid transmission of virus without a latent period and during exploratory feeding probes makes reducing of virus spread by killing incoming aphids with insecticides ineffective.

**PLANT VIRUSES**

**Virus Vector Groups**

Most vectors of plant viruses are sucking insects in the order Homoptera[5] (considered the order Hemiptera by most recent classifications). Their small stylets allow vectors to introduce virus into plant cells or vascular tissues with minimal feeding damage. Aphids (Aphididae) transmit the greatest variety of plant viruses. Next in importance are the whiteflies (Aleyrodidae), followed by the leafhoppers (Cicadellidae) and planthoppers (Fulgoroidea). Some viruses have mealybug vectors (Pseudococcidae), and various other hemipteran families have virus vector species. Only a few viruses are transmitted by thrips (Order Thysanoptera), but their economic impact is internationally important. However, some important viruses require leaf beetle (Chrysomelidae) or weevil (Curculionidae) vectors. Viruses transmitted by beetles (order Coleoptera) seem to be best able to withstand, perhaps even require, the severe tissue damage caused by beetle vector feeding that inoculates the virus into plants. The microscopic bud or gall mites in the family Eriophyidae are the most important of the noninsect arthropods that are virus vectors.

**Persistent Transmission of Viruses and Other Pathogens**

Numerous viruses and other disease agents are transmitted by an infectious vector for many days or even weeks. For example, the beet curly top virus (BCTV)
has only one known vector, the beet leafhopper (*Circulifer tenellus*). Infectious beet leafhoppers transmit the virus after a latent period of only a few hours and continue to transmit for days to weeks. The length of time that they continue to transmit depends on how long they feed on a virus-infected plant to acquire this geminivirus. Beet curly top virus is an example of a persistently transmitted virus that is circulative but does not multiply within the vector. This virus also requires a longer feeding period for vector transmission. Like BCTV, the aphid-borne, persistently transmitted viruses that cause the internationally important diseases barley yellow dwarf and potato leafroll (luteoviruses) can be controlled by effectively timed applications of insecticide that kill aphids shortly after they fly into the crop. Most lengthy latent periods result from the requirement of the pathogens to multiply within the vector to attain the numbers needed to complete the vector transmission process by reaching the salivary glands in sufficient numbers. Some viruses and bacteria multiply within numerous types of organs and tissues within the vector that probably are not required for transmission, and a consequence is that some of these plant pathogens are harmful to the vector. Reoviruses (rice dwarf, for example) multiply within both their insect vectors and plant hosts. Multiplication and circulation of the pathogens within the body cavity (hemocoel) of the vector insures that the pathogen will remain within the vector after molts that occur as the vector develops. Nonpersistently or semipersistently transmitted viruses are no longer transmitted once the vector has molted its exoskeleton.

**NONVIRAL PATHOGENS**

**Vectors and Fungi**

Insect feeding damage can cause wounds that promote the invasion of fungi that damage plants or their fruit. A variety of sucking insects that feed on fruits can introduce the fungus *Nematospora corylii*, which causes yeast spot disease of bean, coffee, cotton, and a variety of other crops. The feeding of a sucking insect, the grape phylloxera, causes lesions on the roots of grapevines that are invaded by soil fungi that deteriorate the roots.

Dutch elm disease is a representative example of a disease caused by a beetle-transmitted fungus, *Ophiostoma ulmi*. The fungus colonizes the wood of living elms or recently killed trees or cut logs, which are also
where the bark beetle larvae develop beneath the elms’ bark. Fungal spores of *O. ulmi* are sticky and attach to the newly emerging adult bark beetles. After flying to other elms, the beetles introduce the spores into feeding wounds on small twigs or into the tunnels excavated under elm bark by the bark beetles for egg laying.[⁵]

The fungus spreads into the tree’s vascular system. Elms weakened by the Dutch elm disease are more attractive for new beetle attacks. Control requires vigilant sanitary measures of quickly removing and destroying diseased elms to eliminate the fungus and reduce the numbers of developing bark beetles.[⁷]

### Trypanosomes and Nematodes

Sucking insects can also vector trypanosomes (flagellated protozoa) that infect various plants, causing especially serious diseases of palms and coffee. Other insect-vectored trypanosomes cause mild or symptomless infections of milkweeds and tomatoes.[⁸]

Wood-boring beetles (Cerambycidae) serve as vectors of nematodes that cause pine wilt disease. Immature nematodes multiply within plant tissues and enter the spiracles of the newly molted adult beetles. The nematodes crawl out of their beetle transporters after the beetles have flown to other trees and excavated egg-laying chambers in the trees’ trunks to lay eggs (Table 1).

### CONTROL OF PLANT DISEASES CAUSED BY VECTOR-BORNE PATHOGENS

The principal methods to control crop disease spread by vectors limit vector acquisition of the pathogen or prevent infective vectors from transmitting to susceptible crops. The impact of insecticides for vector control on disease spread depends on the vector transmission characteristics of the pathogen, as previously discussed. Sanitation is most often used to prevent vector acquisition. This requires the removal of diseased plants or insuring that new plants are free of the targeted pathogen by using certified propagating materials. Physical isolation of crops from exposure to vectors can be used in greenhouses or by growing crops in regions where the vector populations are very low. Varying planting dates can be used to avoid peak periods of vector activity if these can be reliably predicted and do not cause unacceptable losses in yields or quality. Using resistant varieties of plants is a highly effective control if genetic resistance is available. Molecular methods of producing new varieties promise to increase the availability of resistant

Integrated Pest Management

Marcos Kogan
Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

In the context of integrated pest management (IPM), a pest is any living organism whose life system conflicts with human interests, economy, health, or comfort. Pests belong to three main groups: 1) invertebrate and vertebrate animals; 2) disease-causing microbial pathogens; and 3) weeds or undesirable plants growing in desirable sites.

The concept of pest is entirely anthropocentric. There are no pests in nature, in the absence of humans. An organism becomes a pest only if it causes injury to crop plants in the field or to their products in storage or, outside an agricultural setting, if it affects structures built to serve human needs. This article focuses on the impact of pests on plants.

BACKGROUND

Since the beginnings of agriculture some 10,000 years ago, humans competed with other organisms for the same food resources. Primitive tools to fight pests were probably limited to handpicking and methods such as flooding or fire, although at times of despair agriculturists resorted to magic incantations or religious proclamations. But as early as 2500 B.C., Sumerians used sulfur to control insects and by 1000 B.C., Egyptians and Chinese were using plant-derived insecticides to protect stored grain. Real progress in the fight against agricultural pests occurred upon advances in biological sciences, resulting in a better understanding of arthropod pests and the relationships between microbial pathogens and plant diseases. Until the middle of the twentieth century, insect pest control ingeniously combined knowledge of pest biology and cultural and biological control methods. Trichlorodiphenyltrichloroethane (DDT) in the early 1940s ushered in an era of organo-synthetic insecticides. Initial results were spectacular and many entomologists foresaw the day when all insect pests would be eradicated. This optimistic view was premature, as insects quickly evolved mechanisms to resist the new chemicals, requiring more frequent applications, higher dosages, or the replacement of old insecticides with more powerful ones. This cycle has become known as the insecticide treadmill. At the end of the 1950s, scientists around the world became aware of the risks associated with the application of powerful insecticides, as resistance rendered one chemical after the other useless and as beneficial organisms were indiscriminately killed along with target pest species. Such killing of insect parasitoids and predators caused the resurgence of pests at even higher levels. In addition, populations of other plant-eating species, usually balanced by the pests’ natural enemies, exploded in outbreak proportions, causing upsurges of secondary pests and pest replacements. As a result of mounting concern about resistance, resurgence, and upsurges of secondary pests, the concept of integration emerged—an attempt to reconcile pesticides with the preservation of natural enemies.

INTEGRATION

The next phase in the evolution of IPM was the expansion of the term “integrated” to include all available methods (biological, cultural, mechanical, physical, legislative, as well as chemical) and to span all pest categories of importance in the cropping system (invertebrates, vertebrates, microbial pathogens, and weeds). Because of the multiple meanings, integration in IPM was conceived at three levels of increasing complexity. Level I integration refers to multiple control tactics against single pests or pest complexes; level II is integration of all pest categories and the methods for their control; level III integration applies the steps in level II to the entire cropping system. At level III, the principles of IPM and sustainable agriculture converge.

THE ECOLOGICAL BASES OF IPM

Ecology offered the tools to describe how populations expand and contract under natural conditions; how biotic communities are organized and how their component organisms interact; how abiotic (nonliving) factors (climate, soil, topography, hydrology) shape biotic communities; how biodiversity stabilizes ecological systems; and, perhaps most significantly, how to understand the effects of
disturbances in the dynamics of biotic communities.[5,6] Thus, IPM relied upon a solid ecological foundation.[4,5,7]

THE TOOLS OF PEST MANAGEMENT

Management of pests in an IPM system is accomplished through selection of control tactics singly or carefully integrated into a management system. These tactics usually fall into the following main classes: 1) chemical; 2) biological; 3) cultural/mechanical; and 4) physical control methods (these four methods apply to all pests); 5) host plant resistance (applicable to invertebrate and microbial pests); 6) behavioral; and 7) sterile insect technique, a genetic control method (relevant only to insects).

Chemical Control

Chemical pesticides are used to kill or interfere with the development of pest organisms. Pesticides are called insecticides, acaricides, nematicides, fungicides, or herbicides if the target pests are insects, mites, nematodes, fungi, or weeds. Pesticides are useful tools in IPM if used selectively and if the pest population threatens to reach the economic injury level (described later). Much care is necessary to handle pesticides and avoid their potentially negative effect on the environment.[8]

Biological Control

Biological control refers to the action of parasitoids, predators, and pathogens in maintaining another organism’s population density at a lower average than would occur in their absence.[9] In IPM practice, biological control includes intentional introduction of natural enemies to reduce pest population levels (classical biological control), the mass release of biocontrol organisms (inundative biocontrol), or the timely inoculation of natural enemies (augmentative biocontrol).[10]

Cultural Control/Mechanical

Cultural practices become cultural controls when adopted for intentional effect on pests. Thus, tillage and other operations for soil preparation have a direct impact on weeds and on soilborne insect pests. The manipulation of the crop environment to favor natural enemies is called habitat management, and is of growing interest as a form of conservation biological control.[10,11]

Physical Control

Fire, water, electricity, and radiation are some of the main physical forces used in IPM. Flooding in paddy rice cul-
appropriate tactics. In arthropod pest control the criteria are based on assessments of the extant pest population in the field, its damage potential (if not controlled), and the relative costs of treatment and crop value. The main parameters are the economic injury level (EIL) and economic threshold (ET). ET is the population level that will trigger a control action. Fig. 1 describes these parameters. To use ETs it is necessary to monitor pest populations in the field using well-defined sampling methods, which vary with the pest species. Although useful, the concept of EIL is less effective as a decision-making support tool for weed management and is partially applicable for microbial disease management.\[18\]

CONCLUSION

It is difficult to assess the global impact of IMP. It is safe, however, to state that the concept drastically changed the approach to pest control among progressive growers, the chemical industry, research establishments, and policy makers. One of the few economic analyses of the impact of IPM was done in Brazil on soybean production costs. The study suggested that technologies available in 1980 (date of the study), if adopted throughout the entire production area (8.5 million ha), would have resulted in savings of US$216 million annually. Most major agricultural crops have benefited from the adoption of IPM, although IPM is in its infancy and major advances are still to be expected as modern technology comes to be incorporated into the management of all pests.

Intellectual Property and Plant Science

Susanne Someralo
John Dodds

Dodds & Associates, Washington, D.C., U.S.A.

INTRODUCTION

Intellectual property (IP) refers to creations of the human mind. Intellectual property may be inventions, artistic works, designs, names, images, and so on. The basic means to protect intellectual property are patents, copyrights, trademarks, and trade secrets. Plant Breeder’s Right is a specific type of protection for new sexually propagated plant varieties.

Even if the intellectual property rights are largely national rights, there are several international treaties, the most important being the TRIPS agreement (Trade Related Aspects of Intellectual Property Rights), regulating the contents of the national intellectual property laws. In addition to international treaties, there are international organizations such as WIPO (World Intellectual Property Organization) and UPOV (International Union for the Protection of New Varieties of Plants) administering certain intellectual property practices.

In the following article we will briefly go through various means for protection relevant to plant sciences. Thereafter, we will deal with the current issues of intellectual property and modern plant sciences, and lastly we will briefly discuss the development of intellectual property legislation and international treaties affecting it.

MEANS TO PROTECT INTELLECTUAL PROPERTY

The basic means to protect intellectual property are patents, copyrights, trademarks, trade secrets, and Plant Breeder’s Rights. There are variations in the national laws, and some countries provide broader protection than others. For example, a concept of plant patent is specific for the protection system of the United States. A basic understanding of these mechanisms is essential for anyone whose research may lead to an invention.

Patents

Historically, a patent was a grant made by a sovereign that would allow for the monopoly of a particular industry, service, or goods. Over time, the concept has been refined from a public policy perspective and has evolved to an agreement between the government and the inventor/creator.

In return for the right to exclude others from the practice of the invention, the government requests the inventor to fully disclose the enablement of the invention; furthermore, the monopoly is now limited by time and clearly is only applicable in the territory under the jurisdiction of the government.

A patent, as stated above, is an agreement between the government and the inventor, and in the United States a fundamental right is provided in Article I, Section 8, of the Constitution. Congress is empowered to ‘‘...promote the progress of science and useful arts by securing for limited times to authors and inventors the exclusive right to their respective writings and discoveries.’’

In exchange for a limited-term right (usually 20 years) to exclude others from making, using, or selling the invention, the inventor must provide a complete and accurate public description of the invention and the best mode of ‘‘practicing’’ it. This provides others with the ability to use that information to invent further, thus promoting technology development for the benefit of society.

This right to exclude means that a patent is a ‘‘negative right’’ since a patent holder may only exclude others from using, manufacturing, copying, or selling his or her invention.

Copyrights

A copyright is a type of intellectual property protection for ‘‘authors’’ of original works. Basically, a copyright protects an original work and allows the author an exclusive right to reproduce the work, prepare derivatives, distribute copies of the work, and perform the copyrighted work publicly.

Historically, copyrights have been important in protecting the rights of artists and authors. Today, copyrights are becoming more and more important in protecting the rights of database creators. Copyrights may be relevant means of protecting, for example, GIS databases or databases containing gene sequences.
Trademarks

A trademark is a word, phrase, symbol, or design, or a combination of those, that distinguishes the source of one’s goods or services from those of others. A trademark can be valid only when it is used in connection with the goods or services in commerce. Trademarks are important means for distinguishing a product or a technology; for example, plant seeds may be trademarked.

Geographical Indications

Geographical indications are defined in the TRIPS agreement as a type of intellectual property. A geographical indication is a sign used on goods that have a specific geographical origin and possess qualities or a reputation that are due to that place of origin. In the United States, geographical indications are treated as trademarks.

Most commonly, a geographical indication consists of the name of the place of origin of the goods. Agricultural products typically have qualities that derive from their place of production and are influenced by specific local factors, such as climate and soil.

Trade Secrets

Trade secrets are the cheapest way to protect one’s intellectual property: Having a trade secret simply requires that the intellectual property is kept secret. A trade secret could, for example, be composition of a culture medium or a method to transform a plant species.

The positive aspect of trade secrets in addition to their cheapness is that there is no expiration date. However, the negative side is that once the secret is out the protection is gone.

Plant Breeder’s Rights

The TRIPS agreement obliges the member countries to provide protection for plant varieties either through patents or by an effective sui generis system or a combination of them. The most common sui generis system is Plant Breeder’s Rights (PBR). PBR allows the developers of new plant varieties to control multiplication and sale of the reproductive material of a new variety.

Several countries have joined UPOV, established in 1961 and last revised in 1991. UPOV sets forth the minimum requirements that the national protection should grant.

In the United States the right is called Plant Variety Protection (PVP), and it is granted for sexually reproduced or tuber-propagated plants. The term of protection is 20 years for most crops and 25 years for trees, shrubs, and vines.

Plant Patent

Plant patent is a specific type of patent granted in the United States to an inventor who has invented or discovered and asexually reproduced a distinct and new variety of plant species. The provision excludes tuber-propagated plants or plants found in an uncultivated state. Plant patents are issued for 20 years.

CURRENT ISSUES

Patenting Life

The intellectual property system is a dynamic system that needs to be reevaluated in the course of developing technologies and trade practices. The emergence of modern biotechnology more than 20 years ago prompted the U.S. Supreme Court to reevaluate the concept of patentability. In 1980 the Court gave the famous decision stating that a genetically modified bacteria qualifies as patentable subject matter and that “everything under the sun made by man is patentable.” Five years later, the Board of Appeals and Interferences of the U.S. Patent and Trademark Office held that genetically modified plants are patentable. However, as recently as 2001, the U.S. Supreme Court still discussed whether utility patents may be issued for plants. The ruling was that newly developed plant breeds fall within the terms of utility patent. Therefore, a sexually reproduced plant variety may receive a double protection by PVP and by utility patent.

The issue of patentability of transgenic plants is not resolved in Europe yet. The European Patent Office (EPO) acts under European Patent Convention (EPC). EPC prohibits patenting of plant varieties. In 1995 the EPO Board of Appeal held that a transgenic plant was a new plant variety and therefore not patentable. However, cells from the transgenic plant were held to be “microbiological products” and therefore patentable.

The European Biotechnology Directive entered into force on July 30th, 2000. The Directive confirms that biological material per se is not unpatentable. Inventions having the required novelty, inventive step, and industrial applicability shall be patentable even if they comprise biological material or utilize a process by means of which biological material is produced, processed, or used. Therefore, an isolated gene or gene sequence may be patentable provided that its function is known and a suitable industrial application is derived from that product.

According to the Directive, plant and animal varieties are not patentable, but the definition of plant variety is so narrow that most transgenic plants do not fit into it. The European Commission is soon going to release legislation...
for so-called Community Patent that would cover all the member countries. The Community Patent would follow the standard of the Biotechnology Directive and therefore basically allow patenting of transgenic plants.

**Traditional Knowledge**

Traditional knowledge refers to the knowledge, innovations, and practices of indigenous and local communities around the world. Traditional knowledge has been transmitted orally from generation to generation and tends to be collectively owned. Among many other things, agricultural practices, including the development of plant species and animal breeds, may be traditional knowledge. This kind of traditional knowledge is based on genetic resources. The relationship between genetic resources, traditional knowledge, and intellectual property rights is one of the most important issues on the agenda of several international organizations.

The Convention of Biological Diversity (CBD) constitutes the central instrument concerning biodiversity at the international level. CBD affirms the sovereign rights of states to exploit their own resources pursuant to their own environmental policies.

The Convention also provides a broad framework for member states’ policies concerning access, development, and transfer of technologies and acknowledges the necessity for all parties to recognize and protect intellectual property rights in this field. It points to the need for equitable sharing of benefits arising from the use of traditional knowledge, innovations, and practices relevant to the conservation of biodiversity and the sustainable use of its components.

The Food and Agricultural Organization (FAO) adopted the International Treaty on Plant Genetic Resources (ITPGR) in 2001. The objectives of the Treaty are the conservation and sustainable use of plant genetic resources for food and agriculture and the fair and equitable sharing of the benefits arising out of their use, in harmony with the Convention of Biological Diversity, for sustainable agriculture and food security. The contracting parties agree to establish a multilateral system to facilitate access to plant genetic resources for food and agriculture and to share the benefits arising from the utilization of these resources in a fair and equitable way.

The issues related to traditional knowledge are also closely related to IP protection in the developing world. People in many developing countries are asset-poor but knowledge-rich, and poor communities seldom gain from that knowledge. As it might be difficult for indigenous people to invest in conventional IP protection, let alone litigations to protect their IP, new IP protection and contract models may be needed to protect such knowledge and to bring the benefit to the poorest.

**CONCLUSION**

Even if the concept and means for intellectual property are old, the issues emerging with the rapid development of life sciences together with ethical concerns have made it necessary to reevaluate the concept. Presently there are several international organizations trying to create harmonized guidelines for protection of intellectual property in industrialized countries as well as in developing countries. A detailed overview of the current issue of intellectual property rights in agricultural biotechnology is given in recent review.[5] Especially interesting issues are those related to the protection of traditional knowledge.

International Treaties Relevant to the Management of Plant Genetic Resources

H. David Cooper
Convention on Biological Diversity, Montreal, Quebec, Canada

N. Murthi Anishetty
Food and Agriculture Organization of the United Nations, Rome, Italy

INTRODUCTION

Over the last two decades the management of plant genetic resources has become increasingly subject to political debate, and thus international treaties have become more relevant to those working in this area. While the focus has been largely on issues of access to and transfer of genetic resources, benefit sharing, and intellectual property rights, the most relevant treaties have important implications for all aspects of the management of plant genetic resources.

The main international treaties relevant to the management of plant genetic resources are the Convention on Biological Diversity (CBD; Nairobi, May 1992) and the International Treaty on Plant Genetic Resources for Food and Agriculture (Rome, November 2001). These legal instruments have comprehensive provisions for the conservation and sustainable use of, and access to, plant genetic resources, and for the sharing of benefits derived from their use. These and other relevant agreements are briefly reviewed in Table 1.

THE FAO GLOBAL SYSTEM ON PLANT GENETIC RESOURCES

International cooperation on plant genetic resources has been developed primarily in the framework of the Food and Agriculture Organization of the United Nations. The International Board for Plant Genetic Resources was set up at FAO in 1974. Its successor body, the International Plant Genetic Resources Institute (IPGRI), is one of the 16 international agricultural research centers (IARCs) of the Consultative Group on International Agricultural Research (CGIAR) which collectively house the world’s most important network of ex situ collections (see article by Anishetty and Robinson, p. XXX). In 1983, the FAO Conference established the Commission on Plant Genetic Resources as an intergovernmental forum to address all issues related to plant genetic resources and adopted the International Undertaking—a nonbinding agreement which recognized plant genetic resources as the heritage of mankind.⁴ Although qualified by recognition of national sovereignty over genetic resources, the system developed within the framework created by the Undertaking was essentially one based on free access to genetic resources. In 1989, FAO recognized Farmers’ Rights as “‘rights arising from the past, present and future contributions of farmers in conserving, improving and making available, plant genetic resources, particularly those in the centres of origin/diversity.’” In 1994, most of the collections held by the IARCs were brought under the auspices of FAO as part of the international network of ex situ collections and are held “‘in trust’” for the world community. In 1995, the Commission was broadened to become the Commission on Genetic Resources for Food and Agriculture (CGRFA). The Global Plan of Action for the Conservation and Sustainable Use of Plant Genetic Resources for Food and Agriculture (PGRFA) was adopted in 1996 by the International Technical Conference, Leipzig, and subsequently endorsed by the FAO Conference and the Conference of the Parties of the CBD. These and other elements of the FAO “‘global system’” are listed in Table 2.

THE CONVENTION ON BIOLOGICAL DIVERSITY

The CBD, adopted by a diplomatic conference in Nairobi, 1992, is one of the three Multilateral Environmental Agreements to have emerged from the United Nations...
Conference on Environment and Development process. Its objectives (Article 1) are “... the conservation of biological diversity, the sustainable use of its components and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources, including by appropriate access to genetic resources and technology transfer. (Refer to text.)” The Convention applies to biodiversity at three levels: genes, species, and ecosystems. The Conference of the Parties meets regularly (currently every 2 years) to develop guidance and various programs of work and to review implementation of the Convention.

The Convention requires Parties to develop national strategies, plans, or programs for the conservation and sustainable use of biological diversity and, as far as is possible and as appropriate, to integrate them into sectoral and cross-sectoral plans, programs, or policies (Article 6).

</tbody>
</table>

In parentheses the following information is given: date of adoption of the text of the agreement; date of entry into force; number of parties as of 1-08-04. Further information is provided in Refs. [1–3].

The Convention includes specific measures for the conservation of biological diversity, including genetic resources, in situ (Article 8) and ex situ (Article 9). Article 8(j) includes a specific provision to protect the relevant knowledge, innovations, and practices of indigenous and local communities.

Access to Genetic Resources and Benefit Sharing

In its Article 15, the Convention reaffirms national sovereignty over natural resources and establishes that the right to determine access to genetic resources rests with national governments and is subject to national legislation. At the same time, the Convention requires Parties to facilitate access and “not to impose restrictions that run counter to the objectives of the Convention.”
Mutually Agreed Terms

For access to be on MAT, both supplier and recipient must agree to the terms, thus providing an opportunity for the supplying country to negotiate a share of the benefits derived from the use of the genetic resources. Usually, this implies a contractual arrangement, executed on a bilateral basis. The contract often takes the form of a “Material Transfer Agreement” (MTA) setting out the agreed terms on which the genetic material is transferred. The MTA may specify the permitted or prohibited uses of the genetic resources provided, including whether or not it may be commercialized; any rights which may or may not be taken out over the resource or its derivatives; and the benefits that are to be shared.

Prior Informed Consent

Unless the Party determines otherwise, access is also subject to PIC. This means that the responsible authority of the providing country can decide to grant or refuse access following a request from the applicant. In the application, the applicant may be required to provide information concerning the genetic resources required and the purpose for which they are required, as well as any proposal for benefit sharing. As part of the PIC procedure, the responsible authority may consult with indigenous and local communities, or other stakeholders, concerned.

Some 25 countries have already developed laws and other policy measures to regulate access to genetic resources and benefit sharing, and a similar number are planning or considering such measures.\(^a\)

---

\(^a\)Regional groups, national governments, or state governments that already have laws or regulations concerning access to genetic resources and benefit-sharing include the Andean Pact (Bolivia, Colombia, Ecuador, Peru, Venezuela); Australia (the States of Western Australia and Queensland); Brazil (at the Federal level and the States of Acre and Amapa); Bulgaria; Cameroon; Costa Rica; the Gambia; Guyana; India; Kenya; Malaysia (the State of Sarawak); Malawi; Mexico; Nicaragua; Panama; the Philippines; Switzerland; South Africa; Uganda; Vanuatu; and the United States of America (within Yellowstone and other national parks). In some cases there is specific legislation or regulations governing access and benefit sharing; in other cases the laws are only “enabling” in nature, in that they charge a competent national authority to examine the issue and develop specific guidelines or regulations in the future. For further information and updates consult [http://www.biodiv.org/programmes/socio-eco/benefit/measures.aspx](http://www.biodiv.org/programmes/socio-eco/benefit/measures.aspx) or [http://www.grain.org/brl/](http://www.grain.org/brl/).
The Conference of the Parties has adopted a number of programs of work for the implementation of the Convention including a program of work on Agricultural Biodiversity, which is of relevance to the management of genetic resources (Decision V/5; Nairobi, May 2000). The Conference of Parties has also adopted a Global Strategy for Plant Conservation with 16 outcome-oriented targets for 2010 (Decision VI/9; The Hague, April 2002). Of most relevance to plant genetic resources management is target 9: “70 per cent of the genetic diversity of crops and other major socio-economically valuable plant species conserved, and associated indigenous and local knowledge maintained.”

In 2002, the Conference of the Parties adopted the Bonn Guidelines on Access to Genetic Resources and the Fair and Equitable Sharing of the Benefits Arising out of their Utilization (Decision VI/24; The Hague, April 2002), which provide guidance on the development of national legislation and on contracts for benefit sharing, including measures that might be taken by Parties to encourage users of genetic resources to comply with the Guidelines.

Recently, the Conference of the Parties, responding to an invitation contained in the Johannesburg Plan of Implementation of the World Summit on Sustainable Development, initiated a process to elaborate and negotiate the nature, scope, and elements of an international regime on access and benefit sharing (Decision VII/19; Kuala Lumpur, February 2004). This will be carried out by the Convention’s Intergovernmental Working Group on Access and Benefit Sharing. The Working Group will also address measures to support compliance with PIC and MAT (“user measures”), including an international certificate of origin, and the disclosure of origin of genetic resources and associated traditional knowledge in applications for intellectual property rights.

**THE INTERNATIONAL TREATY ON PLANT GENETIC RESOURCES FOR FOOD AND AGRICULTURE**

The International Treaty on Plant Genetic Resources for Food and Agriculture was adopted by the FAO Conference on 3 November 2001 after 7 years of negotiations in FAO’s CGRFA. Most of the negotiations focused on developing a multilateral system of access and benefit sharing for major food crops, and on dealing with issues identified as “outstanding” by the diplomatic conference that adopted the Convention, namely: access to ex situ genetic resources not covered by the Convention, and farmers’ rights. The Treaty entered into force on 29 June 2004.

**The Multilateral System for Access and Benefit Sharing**

As recognized both by the FAO’s CGRFA and the Conference of the Parties of the CBD, a purely bilateral approach to access and benefit sharing is not well suited for the genetic resources of major food crops. This is because, for several reasons, agriculture in all countries depends largely on PGRFA that originated elsewhere; future advances in crop improvements, which are needed for sustainable agriculture and food security, require continued access to a wide genetic base without major restrictions; and because of movements of people and resources over past millennia as well as modern collecting efforts, the genetic resources of major crops already are widely distributed ex situ both in genebanks and in production areas, and thus attribution of country of origin is often very difficult.[5]

Thus the new International Treaty creates a “Multilateral System for Access and Benefit Sharing,” which, for a list of certain plant genetic resources for food and agriculture “established according to criteria of food security and interdependence,” guarantees facilitated access in return for benefit sharing. The list comprises most major food crops (including cereals such as rice, wheat, maize, sorghum and millets; grain legumes such as beans, peas, lentils, chickpeas, and cowpeas; roots and tubers such as potato, sweet potato, cassava, and yams), plus a list of forages (32 genera).

The Treaty provides for facilitated access to material in the Multilateral System for the purposes of food and agriculture research, breeding, and training in this area. A Party is obliged to provide access to PGRFA listed in the Multilateral System on these terms: 1) when requested to do so by another Party, a legal or natural person under the jurisdiction of a Party, or by an international institute that has signed an agreement with the governing body; and 2) when such PGRFA has been acquired under these same terms. Article 13 of the Treaty provides that benefits arising from the use, including commercial use, of plant genetic resources for food and agriculture under the Multilateral System shall be shared fairly and equitably through the exchange of information, access to and transfer of technology, capacity-building, and the sharing of the benefits arising from commercialization. There are special provisions for monetary benefit sharing in the case of commercialization of a product that is a PGRFA and that incorporates material accessed from the Multilateral System: “recipients shall pay to [a] mechanism (…), an equitable share of the benefits arising from the commercialization of that product, except whenever such a product is available without restriction to others for further research and breeding, in which case the recipient who commercializes shall be encouraged to make such
payment.’’ The Treaty also provides for special terms of access to material maintained by the International Agricultural Research Centers (Article 15).

The establishment of a multilateral system is made by the Parties ‘‘in the exercise of their sovereign rights.’’ By agreeing to the terms of the Treaty, countries are, in effect, agreeing that for access to a defined subcategory of PGRFA, PIC would not be required on each and every occasion, but rather that a multilaterally determined set of MATs would apply.

Other Provisions of the International Treaty

This focus on access and benefit sharing notwithstanding, the Treaty has a comprehensive scope. The Treaty calls for an integrated approach to the exploration, conservation, and sustainable use of plant genetic resources for food and agriculture (Article 5), and includes specific provisions on surveying, inventoring, and collecting PGRFA as well as on in situ and ex situ conservation. Explicit reference is given to ‘‘on farm’’ conservation by farmers, as distinct from in situ conservation of wild PGRFA. This is an example of greater specificity in the Treaty as compared to the CBD. The Treaty’s Article 6 requires Parties to develop and maintain appropriate policy and legal measures that promote the sustainable use of plant genetic resources for food and agriculture. Measures for sustainable use include those aimed at improving the use of plant genetic resources through plant breeding by farmers and professional breeders alike, as well as promoting diversity at all levels. Article 7 of the Treaty calls for integration of these activities into agricultural and rural development programs and policies. This complements Article 6 of the CBD for the integration of National Biodiversity Strategies and Action Plans (NBSAPs) into sectoral and intersectoral policies.

Article 9 of the Treaty states that Parties are to ‘‘recognize the enormous contribution that the local and indigenous communities and farmers of all regions of the world, particularly those in the centres of origin and crop diversity, have made and will continue to make for the conservation and development of plant genetic resources which constitute the basis of food and agriculture production throughout the world.’’ The Treaty provides for three substantive elements of Farmers’ Rights including 1) protection of traditional knowledge relevant to plant genetic resources for food and agriculture; 2) the right to equitably participate in sharing benefits arising from the utilization of plant genetic resources for food and agriculture; and 3) the right to participate in making decisions, at the national level, on matters related to the conservation and sustainable use of plant genetic resources for food and agriculture.

The Treaty provides for a funding strategy (Article 18), the objectives of which are ‘‘to enhance the availability, transparency, efficiency, and effectiveness of the provision of financial resources to implement activities under the Treaty.’’ Further, the Governing Body shall periodically establish a target for such funding to mobilize funding for priority activities, plans, and programs, taking the Global Plan of Action into account. The Treaty includes provisions for regular communication between the Governing Body and the Conference of the Parties of the CBD (Article 19). The Conference of the Parties has welcomed the Treaty (Decision VI/9; The Hague, 2002).

The first meeting of the Governing Body of the Treaty is expected to take place in 2005. A number of important decisions will be taken by Parties at this first meeting, including the development of a standard MTA for material in the Multilateral System, the funding strategy, and procedures to promote compliance with the Treaty. The CGRFA, acting as the interim committee for the Treaty, is preparing for this first meeting.

Interphase Nucleus, The

Paul Fransz
University of Amsterdam, Amsterdam, The Netherlands

INTRODUCTION

Most cells of a multicellular organism contain the same genetic information, yet their gene expression pattern, morphology, and function may differ considerably. Cell identity is determined by the nuclear program and established by a complex molecular interplay between DNA sequence and proteins involved in higher order chromatin structure. The organization of the nucleus, therefore, plays a crucial role in cell type and stage-specific processes. The nucleus is a complex organelle showing a high degree of compartmentalization. The linear organization of several eukaryotic genomes is completed, but we know very little about the higher order chromatin structure. Our knowledge of the functional organization of the interphase nucleus is also still very limited. Most of what we know about nuclear architecture comes from microscopic studies with animal cells. Apart from chromatin, a number of subnuclear structures have been characterized, including the nucleolus, splicing-factor compartments, and many different small nuclear foci. The molecular mechanism underlying the nuclear architecture is currently being unravelled in animals, plants, and yeast. Here, the organization of the interphase nucleus in plants is discussed with respect to chromosome structure and function.

CHROMOSOMES OCCUPY NUCLEAR TERRITORIES

The interphase nucleus is the organelle that accommodates the chromosomes and, thus, the majority of the genetic information that makes up a eukaryote organism. In addition, nuclear processes involve maintaining and passing the genetic information by repairing, replicating, and transcribing the DNA sequence. The haploid genome of higher eukaryotes varies between $10^8$ (Caenorhabditis elegans and Arabidopsis thaliana) and $10^{11}$ (Amphiuma and Fritillaria) base pairs. One of the main questions in studies of interphase nuclei is how the eukaryote genome, spanning up to several meters of DNA, fits into a nucleus with a diameter of only a couple of microns. In order to understand nuclear organization it is essential to study individual chromosomes, which occupy the major part of the nucleus as discrete domains. In 1888, Boveri was the first to suggest that interphase chromosomes occupy nuclear territories. One century later, this theory was demonstrated in human cells by chromosome painting using fluorescence in situ hybridization (FISH) with chromosome-specific DNA probes. Chromosome painting appeared impossible in plants with large genomes such as wheat, Vicia faba or Pisum sativum, probably because the complex molecular organization of their genomes includes abundant dispersed repetitive sequences. However, alien chromosomes present in monosomic or disomic addition lines can be successfully visualized by FISH using the alien genomic DNA as probe. This technique is also known as genomic in situ hybridization (GISH). In interphase nuclei of cereals with large genomes, GISH reveals elongated chromosome territories. Plants with small genomes, such as Arabidopsis contain less repeats and have a higher gene density. The low repeat content allows the use of large genomic DNA probes to visualize chromosome-specific regions up to an entire chromosome territory. Differential chromosome painting can monitor position and size of the homologous chromosome territories and subchromosomal regions at subsequent cell cycle stages (Fig. 1).

Although chromosomal territories are discrete nuclear regions, close association of different chromosomes may occur. Long before the FISH technique was developed, fusion of interphase chromosomes was suggested by cytogenetists who analysed plant species such as the crucifers, which contain nuclei with discrete, heterochromatic chromocenters. The FISH technology identified the subchromosomal regions involved in homolog association. In polyploid wheat, but not in its diploid progenitors, homologous centromeres associate in the xylem cells of developing roots. Similarly, in parenchyma cells of Arabidopsis, chromocenters with homologous rDNA repeats associate nonrandomly. Between 10% (chromosome 5) and 75% (chromosome 2) of the homologs associate at their chromocenters. Moreover, correct alignment of homologous regions occurs in 6% ($n = 114$) of the nuclei (Fig. 2A). In comparison association of homologous chromosome territories in mammalian cells was found for gene-dense, small chromosomes. These observations suggest a physical interaction between homologous chromosome territories in somatic cells.
CHROMOSOME ARRANGEMENT

Each chromosome consists of several distinct domains such as the centromere region, telomere, heterochromatin, and euchromatin. The chromosome territory is likely organized in such a way that each chromosomal subregion occupies a specific position corresponding to its function. The pericentromeric heterochromatic regions are generally positioned towards the periphery of the nucleus. The location of telomeres, however, appears variable. Organisms with large genomes (haploid genome size >3000 Mb) generally exhibit a Rabl configuration, is smaller than 3000 Mb, but the chromosomes (1n = 3) are longer than in maize (2540 Mb, 1n = 10), which shows a non-Rabl pattern. The Rabl orientation in wheat (1C = 16000 Mb) and rye (1C = 7500 Mb) corresponds with the elongated chromosome territories in these species. Human chromosomes (1C = 3000 Mb) generally do not show a Rabl orientation, but a polar orientation of chromosome domains with the major heterochromatin segments towards the nuclear periphery has been suggested based on 1) the observation of late-replicating (G band) DNA near the nuclear periphery and 2) electronmicroscopical studies showing a tendency for perinuclear positioning of heterochromatin domains.

CHROMOSOME ORGANIZATION

Several models of higher-order chromatin structures have been proposed based on microscopic investigation of human interphase chromosomes. The basic unit of chromatin is the nucleosome, which consists of the core histone proteins H2A, H2B, H3, and H4, around which approximately 150 bp of DNA is wrapped. The nucleosomes form a 10 nm fiber, which is visible under the electron microscope as a beads-on-the-string arrangement. Higher-order structures of chromat are formed in the presence of histone H1. A chromatin structure, termed the solenoid, has been proposed, which consists of a 30 nm fiber, in which nucleosomes are packaged into a helical coil with six nucleosomes per turn and histone H1 positioned along the central axis of the coil.

Fig. 1 Different cell cycle stages of Arabidopsis parenchyma cells after in situ hybridization with 118 individually labeled BAC DNA clones covering the long arm. (From Ref. 4.) (View this art in color at www.dekker.com.)

Fig. 2 FISH images of Arabidopsis nuclei hybridized with 18 BACs from chromosome arm 4S (see diagram on the left) show aligned chromosome arms (A) and a megabase-sized loop (arrow) covering the entire arm 4S in one of the homologs (B). (View this art in color at www.dekker.com.)
Further winding of nucleosomes into higher organization levels of chromatin generates irregular folding patterns that are difficult to interpret. Structures such as the scaffold or the matrix have been proposed that may form a supportive skeleton keeping the higher-order chromatin loops together. However, the existence of these supportive structures is a matter of debate, because they have been demonstrated only with severe extraction techniques.

In Arabidopsis, nuclei chromosomes have a relatively simple organization. Each chromosome consists of a heterochromatic chromocenter from which euchromatic loops emanate. Chromocenters contain all major tandem repeats and the majority of the dispersed repeats. In contrast, euchromatin loops are gene-rich and range in size from 200 kb up to an entire chromosome arm (Fig. 2B). Together, chromocenter and loops form a chromosome territory (Fig. 4). This chromocenter-loop organization suggests a clear functional differentiation within a chromosome territory. Most of the DNA in chromocenters is heavily methylated, while the tails of histone H3 are methylated at lysine position 9. In contrast, the euchromatin loops contain less methylated DNA and are rich in histone H4 acetylated at lysine positions 5 and 8, and histone H3 methylated at lysine position 4. These modifications of DNA and histones imply that chromocenters represent transcriptionally silent domains, whereas euchromatic loops contain potentially active gene regions.

The model reflects the simple linear organization of the Arabidopsis chromosomes, which contain only 15% heterochromatin, confined to the pericentromeric and the subtelomeric 45S ribosomal regions. The majority of the chromosome consists of gene-rich euchromatin. In comparison, wheat and rye contain more than 95% heterochromatin. Their chromosomes are not likely to have a similar organization.

**Fig. 3** Telomere position (red) in barley (A), tomato (B), and Arabidopsis (C), which have an average chromosome size of 4900 Mb, 950 Mb, and 130 Mb, respectively. The centromere in barley is shown in green opposite to the telomeres, while in tomato and Arabidopsis the centromeres are in the heterochromatin islands. (Fig. 3A is kindly provided by Zuzana Jasencakova.) (View this art in color at www.dekker.com.)

**Fig. 4** The chromocenter-loop model for the organization of Arabidopsis chromosomes. Each chromosome consists of a heterochromatic chromocenter from which euchromatin loops emanate. The loops may span 0.2 kb up to an entire arm of 3 Mb. (View this art in color at www.dekker.com.)
simple chromocenter-loop organization. Based on the genomic sequence, the content of the average chromosome territory of Arabidopsis is estimated at 25 Mbp of DNA with 5200 genes. This is in contrast with the average human chromosome territory, which contains five times more DNA (130 Mbp) but only approximately 1700 genes. Megabase-sized loops have been demonstrated indirectly for the histocompatibility complex locus on human chromosome 6. Whether these loops are equivalent to the loops found in Arabidopsis and whether the chromocenter-loop model also accounts for other eukaryotes remains to be investigated.

CONCLUSION

The description of territories, euchromatin loops, and heterochromatin domains may suggest a rigid, non-flexible nuclear architecture. However, the interphase nucleus and the chromatin structure appear to be highly dynamic. Advanced 3D-fluorescence microscopy has recently provided new tools for studying the dynamics of chromatin. By tagging chromatin proteins with GFP, it is possible to track specific chromosome sites in real time and measure the kinetic properties of protein complexes.[8] Nuclear components are shown to be transient complexes of nucleic acids and proteins that associate and dissociate dependent on internal or external stimuli. We soon will be able to visualize in detail chromatin remodelling in differentiating cells. More and more we tend to consider the nucleus as a membrane-bound bag filled with DNA, RNA, and protein complexes and lacking a solid skeleton. The flexible, higher-order structure of chromatin is controlled by a complex interplay between DNA and protein complexes. Modulation of chromatin structure and function takes place via covalent modification of histone tails by acetylation, methylation, phosphorylation, or ubiquitination.

These modifications affect the composition of chromatin-associated protein complexes and alter the activity of the gene regions.[9] Several chromatin modifiers have been identified and their effect on gene expression demonstrated in different species. For example, methylation of histone H3 at lysine position K9 by histone methyltransferase SUV39 forms a stable mark that is recognized by heterochromatin protein (HP1). This results in binding of HP1 and subsequent spreading of heterochromatin into native chromatin. The same basic molecular mechanism has been reported for yeast, animals, and plants. The characterization of proteins and protein complexes is currently being established, which will eventually lead to the identification of the factors that are responsible for the higher order organization of chromatin in interphase nuclei.

INTRODUCTION

Genetic variability for agronomic traits is a prerequisite for any plant breeding program. To introduce such variability, plant breeders usually employ intervarietal hybridization. However, in several cases, useful variability for certain traits is either limited or lacking in the cultivated species. In these situations, breeders look for diverse sources and resort to interspecific hybridization. The wild relatives of crop plants are an important reservoir of useful genes and offer enormous potential to introduce such genes into cultivated species. Interspecific hybridization has been one of the important plant breeding methods to broaden the gene pool of crops. Numerous examples are available of the production of interspecific hybrids and their utilization in genetics and breeding research. Several pre- or postzygotic barriers hinder the production of interspecific hybrids and the transfer of genes into crops through interspecific hybridization. However, several techniques of chromosome manipulation, tissue culture, (embryo rescue, anther culture, somatic cell hybridization), molecular markers, and molecular cytogenetics can be employed to overcome these barriers.

Interspecific hybridization has provided a wealth of information on genomic relationships among species, nucleo-cytoplasmic interactions, synteny among distant genomes, the nature of reproductive barriers, mechanisms controlling chromosome pairing, chromosome elimination, nuclear restitution, and alien-gene introgression into the genomes of cultivated species. Numerous examples are available on the transfer of useful genes into crop plants through interspecific hybridization. Notable examples include the transfer of resistance to diseases and pests; leaf and stem rust, Hessian fly, green bug in wheat; crown rust and mildew in oat; mosaic virus and blank shank in tobacco; grassy stunt virus in rice; powdery mildew in barley; black arm in cotton; aphid in lettuce; mosaic virus in okra; bacterial wilt and root knot nematode in tomato; late blight and virus A, X, Y in potato; nematode resistance in sugarbeet; wider adaption to warmer and drier region in peas; hardiness in grapes; cytoplasmic male sterility in wheat and cotton; high protein content in wheat; and highly soluble solids and increased salt tolerance in tomato.

CYTOGENETICS OF INTERSPECIFIC HYBRIDS AND THEIR DERIVATIVES

Interspecific hybrids and their derivatives exhibit peculiar features such as hybrid inviability, hybrid sterility, hybrid breakdown, limited recombination, and linkage drag. Factors such as genomic disharmony, nuclear instability, unfavorable nuclear-cytoplasmic interactions, the presence of deleterious genes, chromosome elimination, allocycly, and centromeric affinity account for limited progress in introgression of useful genes through interspecific hybridization (Table 1). As an example, Fig. 1 shows production of interspecific hybrids through embryo rescue between distantly related species of Oryza.

Hybrid Sterility

Hybrid sterility may be due to differences in structure and number of chromosomes, lack of chromosome homoeology resulting in a variable number of univalents, and production of unbalanced gametes. There are numerous reports of sterile interspecific hybrids and their derivatives. This kind of sterility could be due to gene substitutions and/or cryptic structural differences. Crosses between species with similar genomic constitutions (Oryza sativa × Oryza glaberrima; Oryza sativa × Oryza longistaminata) are highly sterile.

Allocycly or Genomic Disharmony

The parental genomes in interspecific crosses generally show disharmony resulting in meiotic instability, aneuploidy, and unbalanced gametes, and thus to increased sterility and reduced grain yield. Differences in the cell-cycle rhythm of parents, genomic ratio, presence of telomeric heterochromatin, and the cytoplasm donor may contribute singly or collectively to disharmony of the two genomes.

Nuclear Instability

Nuclear instability refers to any deviant nuclear behavior producing a nucleus (or nuclei) of abnormal structure,
karyotype, or behavior. Nuclear instability and mitotic abnormalities in coenocytic endosperm affect seed fertility and endosperm development in triticale. Nuclear instability in triticale endosperm often begins with the formation of a chromatin bridge at anaphase. Restitution nuclei result in degenerated endosperm. The probable cause of nuclear instability may be the higher DNA content in rye. Unlike wheat chromosomes, rye chromosomes have large telomeric segments of heterochromatin. Late-replicating DNA (mostly telomeric heterochromatin) in rye chromosome may cause bridge formation at anaphase. Such bridges may cause the production of abnormally polyploid endosperm nuclei leading to sterility. First-division restitution (FDR), second-division restitution (SDR) in potato, and indeterminate meiotic restitution (IMR) in lily are common features of interspecific crosses.

### Hybrid Breakdown and Reversion to Parental Types

The phenomenon of hybrid breakdown refers to situations where the F₁ is fertile but segregants in the F₂ or later generations are weak or sterile. The phenomenon of hybrid breakdown is not well understood; probable causes include centromeric affinity, cryptic structural hybridity, gene substitution, and unfavorable nuclear-cytoplasm interactions.

Limited Recombination

Reduced chromosome pairing and lack of recombination between genomes of alien and cultivated species are key factors limiting alien gene transfer. The extent of recombination depends on the genetic homoeology of two genomes, which may be different for different chromosomes or chromosome segments. Until precise methods for inducing or enhancing homoeologous recombination and allosyndetic pairing become available, it will be difficult to transfer alien genes into commercial varieties.

Presence of Deleterious Genes and Linkage Drag

Breeders in general are reluctant to use wild species for the improvement of cultivated species because of linkage
drag, wherein some undesirable characters of wild parents are transferred along with useful genes. Some interspecific derivatives (such as Transec) have not been used extensively in wheat breeding because they are associated with lowered yield. Similarly, the Agatha strain of wheat (possessing rust resistance from *Agropyron*) shows undesirable association with yellow flour color. A number of available wheat lines with substituted chromosomes of *Aegilops*, *Agropyron*, and *Secale* have disease and pest resistance or high protein. However, only a few of them are widely used in cultivar improvement because of linkage drag.

**ALIEN GENE TRANSFER**

Major advances have been made in understanding genomic relationships, genetic control of chromosome pairing, and characterization of alien chromatin in interspecific derivatives. Methods have been developed for incorporating complete alien genomes (amphiploids), single chromosomes (alien addition/substitution), small chromosome segments (alien translocations), or a few alien genes from wild into cultivated species. Numerous examples are available of alien gene transfer into crop plants.[2,4,5]

**Synthetic Amphiploids**

A majority of the interspecific hybrids show sterility to varying degrees. Fertility can be restored by doubling the chromosome number of F₁ hybrids (amphiploid production). The other option is to backcross with the recurrent parent until fertile progenies (introgression lines) with stable chromosome number become available. Several amphiploids of hybrids involving cultivated species and wild relatives have been produced during the last 45 years, especially since the discovery of colchicine. With the exception of triticale, however, none has become a new crop.

In amphiploids such lack of genomic harmony causes meiotic instability and several other undesirable features resulting from nuclear-cytoplasmic interactions. However, they are important for extracting desirable derivatives involving crosses of natural × synthetic allopolyploids.

**Extracted Allopolyploids**

Several amphiploids in wheat, cotton, tobacco, and *Brassica* have been used to extract stable allopolyploids through intercrosses of synthetic × natural allopolyploids. Triticale is the classic example for demonstrating the usefulness of extracted polyploids. The hexaploid triticcales extracted from the progenies of 8x triticale × 6x triticale and 6w wheat × 6x triticale are cytologically more stable. They are superior to the primary triticcales in meiotic stability, grain yield, and grain quality.

The production of amphiploids, alien chromosome addition and substitution lines, and backcross (introgression) progenies are important genetic stocks for transferring alien genes to crop plants. Once these stocks are available, they can be further manipulated by directed chromosome engineering.

**Characterization of Alien Chromatin in Interspecific Derivatives through C-Banding and In Situ Hybridization**

Several methods are available to characterize alien chromatin in interspecific hybrids and their derivatives. Morphological traits, isozyme, molecular markers, C-banding, fluorescence in situ hybridization (FISH), and genomic in situ hybridization (GISH) have been employed to characterize parental genomes, extra alien chromosome, translocated chromosome segments, and introgressed genes. Fiber FISH can further enhance the precision for characterization of homoeologous pairing in interspecific hybrids and their derivatives. C-banding has been employed to characterize changes in karyotype and alien chromosome translocations.[6] Several kinds of molecular markers, BAC and YAC, including repetitive DNA; total genomic DNA; and species-specific markers, have been used in characterizing alien chromatin in a great number of interspecific derivatives.

**RESEARCH PRIORITIES AND OUTLOOK ON INTERSPECIFIC HYBRIDIZATION**

With advances in tissue culture, genomics, and molecular cytogenetics the outlook for interspecific hybridization in crop improvement seems more promising. Following are some priorities for future research on interspecific hybridization.

**Map-Based Cloning of Gene(s) Controlling Chromosome Pairing**

Isolate *Ph* gene(s) and introduce into other crops that lack a similar system to promote homoeologous recombination. As in the case of wheat, there is a need to identify pairing controlling genes in crops such as *Brassica*, cotton, rice,
Identifying and Introgressing Chromosome Regions in Wild Species Carrying Novel Alleles for Enhanced Yield Potential

Molecular analyses of mapping populations derived from interspecific crosses have revealed novel QTLs—yield-enhancing loci. Molecular-marker technology should be used to identify and introgress such novel alleles from wild species into cultivated species.

Physical Mapping Using Alien Chromosome Addition Lines and Radiation Hybrids

Partial hybrids or alien addition lines have been produced through chromosome elimination from oat × maize crosses. Such cytogenetic stocks and radiation hybrids should be developed in other systems. Species-specific DNA sequences, retroelements, chromosome-specific markers, and GISH could be used in the physical mapping of genomes of crop plants.

Identifying Agronomically Important Gene-Rich Chromosome Regions

Identify gene-rich regions in different species. Physical mapping of such genes would provide useful information on the possibility for map-based cloning and introgression into genomes of cultivated plants. Genes in the proximal region of chromosomes may be difficult to introgress because of limited recombination. New methods of tissue culture or transposons should be used to transfer such genes into elite germplasm.

Enhancing Chromosomal Exchanges through Tissue Culture among Genomes of Cultivated and Distantly Related Species

Induce chromosomal exchanges between genomes of species that otherwise lack chromosome pairing. Tissue culture of interspecific (sexual and somatic) hybrids and alien addition lines is suggested to achieve this.

FISH-Assisted Selection for Alien Recombinants

Advances in GISH/FISH have made it possible to characterize lines carrying alien chromatin. Emphasis should be given to develop protocols to select interspecific derivatives in early generations based on GISH, important for the recovery of recombinants and to enhance the selection efficiency of alien gene introgression.

Characterizing Genomic Relationships and Microsynteny among Species

Conventional cytogenetic techniques have provided a wealth of information on the genomic homoeology and evolutionary relationships of different species. Molecular cytogenetic techniques involving molecular markers, GISH, FISH, and fiber-FISH should be used to understand precisely the nature and extent of cryptic structural differences, microsynteny, and homoeologous pairing during early meiotic divisions among distant genomes to enhance the efficiency of alien gene introgression.

Producing Haploids from Interspecific Crosses through Chromosome Elimination

Chromosome elimination through species crosses has proven to be a valuable mechanism to produce haploids in wheat, barley, and oat. Haploid-inducing systems need to be identified in other crops such as Brassica, cotton, rice, and legumes. This would be an important complementary approach to produce haploids where anther culture response is limited to only specific genotypes.

Broadening Gene Pool of Crops for Tolerance to Major Biotic and Abiotic Stresses

An integrated approach using tissue culture, molecular markers, and molecular-cytogenetic techniques should be used to monitor alien chromatin and introgress useful genetic variability from wild species into crop plants through interspecific hybridization.

Isoprenoid Metabolism

Russell K. Monson
Todd N. Rosenstiel
University of Colorado, Boulder, Colorado, U.S.A.

INTRODUCTION

Plants synthesize a wide range of molecules with complex structural and functional attributes from the branched, five-carbon monomer precursor known as the isoprene unit. Isoprenoid molecules range in size from those with 5 carbon atoms (the hemiterpenes) to those with more than 40 carbon atoms (the polyterpenes). The various isoprenoid groups have a broad range of functions in plants, including those associated with herbivore deterrence, metabolic electron transport, and hormonal activity. Isoprenoid compounds are used in numerous ways to support human activities, including their use as food flavoring agents (e.g., mint essential oils), perfumes (e.g., monoterpenes), pharmaceuticals (e.g., the antitumor compound, taxol), and insecticides (e.g., pyrethrins). Isoprenoid compounds also have important roles in ecological interactions, including their role in plant–insect interactions (e.g., as antiherbivore agents and as attractants for pollinators and parasites alike) and as allelopathic agents. Recently, it has become clear that the loss of volatile isoprenoid molecules from plants has important ramifications for atmospheric processes. These molecules cause much of the active photochemistry that occurs in the lower atmosphere, including those reactions that lead to tropospheric ozone production and the oxidation of methane, a potent greenhouse gas.[1,2]

BIOSYNTHESIS OF ISOPRENOID PRECURSORS

All isoprenoids are biosynthesized from just two 5-carbon (C5) metabolic precursors: isopentenyl diphosphate (IPP) and its allylic isomer, dimethylallyl diphosphate (DMAPP) (Table 1). Until recently, the biosynthesis of these precursors in plant cells was thought to occur exclusively via the well known mevalonic acid pathway, as occurs in yeast, fungi, and animal cells. However, several recent studies have suggested that a novel non mevalonate pathway of isoprenoid biosynthesis operating in certain bacteria, green algae, and plants.[3,4] The discovery and partial elucidation of the deoxyxylulose phosphate (DOXP) pathway represents one of the most exciting advances in basic plant physiology to occur near the closure of the 20th century.

In plant cells, IPP synthesis not only results from two independent biochemical pathways, but these pathways occur in distinct cellular compartments (Fig. 1). The mevalonate route to isoprenoids appears to reside solely in the cytosol-endoplasmic reticulum (ER) compartment where sterols, sesquiterpenes (C15), triterpenes (C30), and polyterpenes are synthesized. Hemiterpenes—such as isoprene (C5), monoterpenes (C10), diterpenes (C20), and tetraterpenes (C40) as well as the side chains of plastoquinone and α-tocopherol—are synthesized in plastids from IPP formed predominately via the DOXP pathway. A third cellular compartment, the mitochondrion, also participates in isoprenoid biosynthesis by using IPP from the cytosol-ER pathway to make the prenyl side chain of ubiquinone, a component of this organelle’s electron transport chain. This extensive subcellular partitioning of biochemical pathways and products highlights the significant role of compartmentation in plant isoprenoid metabolism. However, the compartmental separation of the two different IPP biosynthetic pathways is not absolute because plastids may supply IPP to the cytosol for use in biosynthesis and vice versa. For example, the first two C5 units of the sesquiterpenes of chamomile are formed via the DOXP pathway, whereas the third unit is derived from both biosynthetic routes.[4] Although crosstalk between the two pathways appears to be small (<1%), elucidation of the nature of the metabolites exchanged between the compartments and regulation of this process remains a significant challenge to plant biochemists.

The biochemical steps involved in the formation of IPP via the mevalonic acid pathway have been firmly established and are known to result from the stepwise condensation of three molecules of acetyl coenzyme A, as occurs in yeast, fungi, and animal cells. However, several recent results have been inconsistent with the mevalonate pathway led to the discovery of an additional non mevalonate pathway of isoprenoid biosynthesis operating in certain bacteria, green algae, and plants.[3] The discovery and partial elucidation of the deoxyxylulose phosphate (DOXP) pathway represents one of the most exciting advances in basic plant physiology to occur near the closure of the 20th century.
The DOXP pathway of IPP formation in plastids begins with pyruvate and glyceraldehyde 3-phosphate. In this pathway, pyruvate reacts with a thiamine pyrophosphate (TPP) cofactor to yield a two-carbon molecule, hydroxyethyl-TPP, which condenses with glyceraldehyde 3-phosphate. TPP is released to form a five-carbon intermediate, 1-deoxy-D-xylulose 5-phosphate (for which the pathway receives its name), which is rearranged and reduced to form 2-C-methyl-D-erythritol 4-phosphate and subsequently is transformed to yield IPP. The enzymes and corresponding gene sequences of the first five steps in the new pathway are now fairly well documented.\[5\] However, the genes, enzymes and reactions involved in the final steps leading to IPP and DMAPP formation remain unknown.

The identification of the regulatory steps of the DOXP pathway is an issue of major importance for both theoretical and applied reasons. So far, efforts have focused on the first two enzymes of the pathway (1-deoxy-D-xylulose 5-phosphate synthase, DXS; and 1-deoxy-D-xylulose 5-phosphate reductoisomerase, DXR) and preliminary results indicate both enzymes may contribute to regulating

![Fig. 1](https://www.dekker.com) Compartmentation of isoprenoid biosynthesis in higher plants between the cytosol (mevalonic acid pathway) and plastids (DOXP pathway). The role of cytosolic IPP in the formation of mitochondrial ubiquinones is also indicated. Abbreviations used: DMAPP, dimethylallyl diphosphate; IPP, isopentenyl diphosphate; GPP, geranyl diphosphate; FPP, farnesyl diphosphate; GGPP, geranylgeranyl diphosphate; HMGR, HMG-CoA reductase, DXS, deoxyxylulose phosphate synthase; DXR, deoxyxylulose phosphate reductoisomerase. (View this art in color at www.dekker.com.)
plant isoprenoid production. Transgenic manipulation of the DOXP pathway holds much promise for the production of commercially important isoprenoids. In one unique example, overexpression of DXR in peppermint led to a dramatic increase in total essential oil accumulation.\[^{[6]}\] Similar successes in the genetic engineering of isoprenoid metabolism have been achieved in the area of isoprenoid vitamins, including α-tocopherol (vitamin E) production in oilseeds and enhanced β-carotene in rice and rapeseed. Because the DOXP pathway is uniquely restricted to plants and certain bacteria (particularly human pathogens), selective inhibition of the DOXP pathway might be the basis for the development of new herbicides as well as novel antibiotics and antimalarial agents.\[^{[7]}\] Despite rapid advances in our understanding of the novel DOXP pathway, significant uncertainties remain. Because constraints on precursor flow will ultimately limit the effectiveness of transgenes for isoprenoid synthesis, information about the flux controls on IPP and DMAPP formation as well as the source of carbon precursors supplying the DOXP pathway is sorely needed.

THE ISOPRENE RULE AND FORMATION OF ALLYLIC DIPHOSPHATE ESTERS

In 1910, the German chemist Otto Wallach was awarded the Nobel Prize in Chemistry for elucidation of the isoprene rule. Simply stated, the isoprene rule revealed that isoprenoid molecules in plants are synthesized by repetitive head-to-tail condensations of a five-carbon, alkene monomer. This rule was modified in the 1930s by Leopold Ruzicka to give the biogenetic isoprene rule, which stated that an isoprenoid molecule is one that is derived from an isoprenoid precursor, even if it undergoes subsequent chemical modification that results in a product with obscure connections to its isoprene origins. Ruzicka was awarded the Nobel Prize in Chemistry in 1939. Thus, the history of isoprenoid chemistry in plants has a rich award-winning legacy.

The head-to-tail condensation of IPP by prenyltransferase enzymes forms three types of allylic diphosphate ester compounds—geranyl diphosphate (GPP), farnesyl diphosphate (FPP) and geranylgeranyl diphosphate (GGPP)—which are subsequently converted into a broad range of terpenes by various terpene synthase enzymes. In the first step of allylic diphosphate ester compounds, IPP is converted to dimethylallyl diphosphate (DMAPP) by IPP isomerase. In the presence of a divalent metal cation, the allylic double bond of the DMAPP molecule forms a resonance-stabilized carbocation that can subsequently react with a second IPP molecule to form GPP (C_{10}) (Fig. 2). Further addition(s) of IPP forms FPP (one additional IPP) or GGPP (two additional IPPs).

TERPENE SYNTHASE ENZYMES

The production of terpenoid compounds from GPP, FPP of GGPP involves an initial ionization to promote cyclization, the primary catalyst being terpene synthase (or terpene cyclase) enzymes. (Acyclic terpenes are known to exist, but most are cyclic.) Many terpene synthases catalyze the synthesis of multiple terpene products; this is permitted because of the multiple fates that are possible for the carboxylation intermediate that is formed from the cyclization catalyzed by terpene synthases.\[^{[8]}\] Over thirty different terpene synthases from angiosperms and gymnosperms, with roles in both primary and secondary metabolic pathways, have been identified on the basis of cDNA sequences. Sequence analysis has revealed that the evolutionary diversification of terpene synthases has occurred through gene duplication and divergence of enzymes; the primary direction of diversification appears to be from ancestral genes involved in primary metabolism toward derived genes involved in secondary metabolism.\[^{[9]}\] Given the ubiquitous distribution of terpene synthase genes in plants, it is likely that future phylogenetic studies of divergent plant groups will benefit from studies of sequence homology among terpene synthase genes.

THE ISOPRENOID CONNECTION TO ATMOSPHERIC CHEMISTRY

In 1960, Fritz Went recognized the potential for plants to add large amounts of volatile isoprenoid molecules to the atmosphere; using the concentration of terpene-containing leaf oils in sagebrush, he estimated global terpene emissions to represent 175 Tg C y^{-1} (1 Tg = 10^{12} g).\[^{[10]}\]
More recent estimates suggest that as much as 500–1000 Tg C y\(^-1\) may enter the atmosphere as volatile isoprenoid compounds.\(^{[11]}\) Although estimates of the global magnitude of these emissions contain many uncertainties, it is clear that the emissions have a profound effect on photochemical reactions in the lower atmosphere. Isoprene, which is formed in the leaves of many tree species, has a boiling point of 39°C, causing it to volatilize from leaves at high rates immediately after being formed. Once in the atmosphere, isoprene has an average lifetime of only 0.2 hours before its double bonds are oxidized by reaction with hydroxyl radicals. A similar fate exists for monoterpane molecules that escape their storage reservoirs in the leaves and enter the atmosphere. The oxidation of isoprenoid molecules by OH causes an increase in the lifetime of CH\(_4\), a compound with strong potential to cause climate warming, because the primary path for the oxidative breakdown of CH\(_4\) also requires OH molecules. The atmospheric oxidation of isoprenoid molecules forms a series of secondary compounds, which participate in even further chemical oxidation. The net result of these oxidations is the formation of organic peroxy compounds, which can react with NO to form NO\(_2\) and ultimately promote the reaction of NO\(_2\) with O\(_2\) to form tropospheric O\(_3\), an important pollutant and radiatively active greenhouse gas. Globally, the emission of isoprenoid molecules from plants is estimated to promote a 30% increase in tropospheric O\(_3\) and to increase the lifetime of CH\(_4\) by 15%.\(^{[12]}\)

**CONCLUSION**

The formation of isoprenoid molecules in plants has important ramifications for issues associated with agriculture and human nutrition, plant adaptation to stress, and global ecology. Studies of the metabolic pathways leading to isoprenoid molecules have revealed several fundamental principles of plant biochemistry, and have provided the foundation for highly recognized scientific research. These fundamental discoveries will allow future research on this topic to focus on the genes that control the expression of isoprenoid biochemistry and permit transgenic approaches to be developed for the manipulation of isoprenoids in various plant tissues.

INTRODUCTION

*Bacillus thuringiensis* (Bt) produces a parasporal, proteinaceous, crystalline inclusion during sporulation. This inclusion is solubilized and hydrolyzed in the midgut of larvae of susceptible insects, releasing polypeptide toxins that cause death.[1–3] Distinct insecticidal crystal protein (IPC) *cry* genes code for larvicidal Cry proteins: Cry1 and Cry2B proteins are specifically toxic to Lepidoptera, Cry2A proteins to Lepidoptera and Diptera, Cry3 proteins to Coleoptera, and four Cry4 proteins to Diptera. Two genes (*cytA*, *cytB*) that code for cytolytic proteins (CytA, CytB) are present with the Cry4 proteins. Some ICPs exhibit activity against Homoptera, Hymenoptera, Orthoptera, Mallophaga, nematodes, mites, *Collembola*, protozoa, and other organisms.[1–3]

DISCUSSION

Sprays of Bt containing cells, spores, and ICPs have been used as insecticides for more than 30 years with generally no unexpected toxicities, probably because Bt does not survive or grow well in soil, and its spores are rapidly inactivated by ultraviolet (UV) light.[1,2,4,5] Hence, there is little production of the proteins in soil, and persistence of introduced toxins is a function primarily of the 1) amount added, 2) rate of consumption and inactivation by insect larvae, 3) rate of degradation by microorganisms, and 4) rate of abiotic inactivation. However, when genes that code for these proteins are genetically engineered into plants, the proteins continue to be synthesized during growth. If production exceeds consumption, inactivation, and degradation, toxins could accumulate and enhance control of target pests; constitute a hazard to nontarget organisms, such as the soil microbiota, beneficial insects, and other animals; and result in the selection and enrichment of toxin-resistant target insects.[1,4–6] Persistence is enhanced when the proteins are bound on surface-active particles (e.g., clays and humic substances) in soil and, thereby, rendered less accessible for microbial degradation, although toxicity is retained.[4,5]

Potential hazards and benefits are affected by modifications (e.g., truncation, rearrangement of codons)[2] of introduced *cry* genes to code only for synthesis of “active” toxins, or a portion of the toxins, rather than code for synthesis of nontoxic ICPs. Consequently, it will not be necessary for an organism to have a high midgut pH (ca. 10.5) for solubilization of ICPs and specific proteolytic enzymes to cleave them into toxic subunits. Nontarget insects and organisms in higher and lower trophic levels could, therefore, be susceptible, leaving only the third barrier apparently responsible for host specificity; i.e., specific receptors on midgut epithelium that are often, but not always, present in larger numbers in susceptible larvae.[1,2,5]

Binding of toxins from *B. thuringiensis* subsp. *kurstaki* (Btk, 66 kDa, active against Lepidoptera), subsp. *tenebrionis* (Btt, 68 kDa, active against Coleoptera), and subsp. *israelensis* (Bti, 25–130 kDa, active against Diptera) on montmorillonite (M) and kaolinite (K); clay-, silt-, and sand-size fractions of soil; humic acids from different soils; and complexes of clay-humic acid-Al hydroxy polymers have been studied.[4,5] M and K are predominant clay minerals in many soils and differ in structure, physicochemical characteristics, and effects on biological activity.[7] The purpose of these in vitro studies, the results of which are summarized in Table 1, was to determine whether toxins in transgenic Bt plants or ICPs in sprays are bound on surface-active soil particles and whether binding results in the proteins becoming resistant to biodegradation and to persist while retaining larvicidal activity.[4,5]

INTERACTIONS IN SOIL OF LARVICIDAL PROTEINS IN TRANSGENIC Bt PLANTS

Biodegradation of Biomass of Bt Plants

Addition of biomass from transgenic corn (*Zea mays* L.) expressing Cry1Ab protein resulted in a significantly lower gross metabolic activity (as measured by CO₂ evolution) of soil than addition of isogenic nontransgenic biomass (Flores, Saxena, and Stotzky, unpublished).[4,5]
Soils amended with biomass of Bt corn were lethal to larvae of the tobacco hornworm (*Menduca sexta*), whereas there was essentially no mortality with soils amended with biomass of non-Bt corn or unamended. Similar results were obtained with biomass of Bt rice, cotton, canola, tobacco, and potato.

The lower biodegradation of Bt corn biomass was not the result of differences in the C:N ratio of the biomasses, as altering the ratio did not significantly alter the relative differences in biodegradation. It was apparently not the result of inhibition of the soil microbiota, as numbers of culturable bacteria and fungi and the activity of enzymes representative of those involved in the degradation of plant biomass were not significantly different in soil amended with biomass of Bt as opposed to non-Bt corn. These results confirmed in vitro observations that the Cry proteins from Btk, Btt, and Bti were not toxic to pure and mixed cultures of microbes and in situ observations of no consistent and lasting effects of biomass of transgenic Bt plants on the soil microbiota.

### Lignin Content of Bt Plants

The lignin content of 10 hybrids of Bt corn was 33–97% higher than that of their respective non-Bt near-isolines. It was significantly higher in plants transformed by event Bt11 than by event MON810; the lignin content of the only available hybrid transformed by event 176 was lowest. There were no significant differences among isogenic non-Bt hybrids. However, the lignin content of the biomass of the other plant species, which was considerably lower than that of corn, was not significantly different in Bt and non-Bt plants. Hence, the higher lignin content of Bt corn may not be an important factor in its lower biodegradation. Nevertheless, modifications in lignin content could have ecological implications, e.g., higher lignin content in Bt corn may provide greater resistance to attack by second-generation European corn borer; reduce susceptibility to molds; and retard litter degradation and decomposition, which may be beneficial, as organic matter from Bt corn may persist and accumulate longer and at higher levels, thereby improving soil structure and reducing erosion. By contrast, longer persistence may extend the time the toxin is present in soil and enhance the hazard to nontarget organisms and selection of toxin-resistant target insects.

### Release of Cry Proteins in Root Exudates

Cry1Ab protein was released in root exudates from 13 hybrids of Bt corn (transformation events Bt11, MON810, and 176). Presence of the toxin in sterile hydroponic culture was indicated by a major band migrating on sodium dodecyl sulfate polyacrylamide gel electrophoresis to a position corresponding to a molecular mass (M_r) of 66 kDa, the same as that of Cry1Ab protein, and confirmed by immunological and larvicidal assays. After 25 days, when the hydroponic culture was no longer sterile, the 66-kDa band was not detected (there were several new protein bands of smaller M_r) and immunological and larvicidal assays were negative, indicating that microbial proteases had hydrolyzed the protein. By contrast, toxin was detected after 180 days—the longest time studied—from Bt corn grown in nonsterile soil in a plant-growth room, confirming that toxin was bound on surface-active soil particles, which protected it from hydrolysis.

To estimate the importance of clays and other physicochemical characteristics—which influence activity and

---

**Table 1** Summary of interactions of purified Bt toxins with surface-active particles: Effects on persistence and larvicidal activity

- Larvicidal proteins from *Bacillus thuringiensis* subsp. *kurstaki* (Btk; antilepidopteran), *tenebrionis* (Btt; anticoleopteran), and *israelensis* (Bti; antidipteran) bound rapidly and tightly on clays, humic acids, and complexes of clay-humic-acid-Al hydroxypolymers; binding was pH dependent and greatest near the isoelectric point (pI) of the proteins; binding of the toxin from Btk was greater than binding of the toxin from Btt, even though the M_r of both was similar (66 and 68 kDa, respectively).
- Bound toxins retained their structure, antigenicity, and insecticidal activity.
- Intercalation of clays by the toxins was minimal.
- Biodegradation of the toxins was reduced when bound; microbial utilization of the toxins as a source of carbon was reduced significantly more than utilization as a source of nitrogen.
- Larvicidal activity of bound toxins was retained.
- Larvicidal activity of the toxin from Btk was detected 234 days after addition to nonsterile soils (longest time studied).
- Persistence of larvicidal activity was greater in acidic soils, in part probably because microbial activity was lower than in less acidic soils; persistence was reduced when the pH of acidic soils was raised to ca. 7.0 with CaCO_3_.
- Persistence was similar under aerobic and anaerobic conditions and when soil was alternately wetted and dried.
- Persistence in soil was demonstrated by dot-blot enzyme-linked immunosorbent assay (ELISA), flow cytometry, Western blots, and larvicidal assays.
- Toxins from Btk, Btt, and Bti had no microbiostatic or microbicidal effect against a spectrum of bacteria (gram positive and negative), fungi (filamentous and yeast), and algae, neither in pure nor in mixed cultures.
ecology of microbes in soil[5,7,10] — to persistence of toxin released in root exudates, studies were done in soil amended to 3, 6, 9, or 12% with M or K. Forty days after germination, all samples of rhizosphere soil from Bt corn were immunologically positive for the Cry1Ab protein and toxic to larvae of M. sexta, whereas there was no significant mortality with soil from non-Bt corn or without plants.[9] The weight of surviving larvae exposed to soils from Bt corn was 50–92% lower than the weight of larvae exposed to soils from non-Bt corn or without plants.

Larvicidal activity was higher initially in soil amended with M than with K, probably because M—a swelling 2:1, Si:Al, clay with a significantly higher cation-exchange capacity and specific surface area than K, a nonswelling 1:1, Si:Al, clay—bound more toxin in root exudates, as also observed with pure toxin.[4,5] However, mortality was essentially the same after 40 days, indicating that over a longer time, persistence of larvicidal activity appeared to be independent of clay mineralogy and other physicochemical characteristics of soils, and that toxin was concentrated when adsorbed on surface-active soil components.

Immunological and larvicidal assays of rhizosphere soil from Bt corn grown in the field were also positive, even in soil collected after frost from plants that had been dead for several months.[5,9] There were no consistent differences in exudation of toxin between hybrids derived from different transformation events, neither in the plant-growth room nor in the field.

In addition to toxin introduced to soil in plant biomass after harvest and in pollen during tasseling,[11] toxin will be released to soil from roots during growth of Bt corn, which could improve control of insect pests, enhance selection of toxin-resistant target insects, and/or constitute a hazard to nontarget organisms. Because Bt corn contains truncated genes that encode toxin rather than nontoxic ICP, potential hazards are exacerbated. This is because it is not necessary for an organism to have a high gut pH and specific proteases, and receptors for toxin are present in target and nontarget insects.[1] Consequently, nontarget insects and other organisms in higher and lower trophic levels could be susceptible.[5]

Cry1Ac protein was not detected in hydroponic culture or nonsterile soil in root exudates of Bt cotton, canola, or tobacco, whereas Cry1Ab protein was detected in root exudates of Bt rice. Cry3A protein was detected in root exudates of Bt potato immunologically and by their toxicity to larvae of the Colorado potato beetle (Leptinotarsa decemlineata) (Saxena and Stotzky, unpublished). It is not clear how such large proteins (e.g., the 66-kDa Cry1Ab protein) are released intact from roots, because the release of molecules with high M, usually requires the presence of a “signal peptide.”[12] The endoplasmic reticulum is apparently close to or associated with the plasma membrane in roots of corn and, perhaps, of rice and potato but apparently not of cotton, canola, or tobacco. Although some toxin from corn, rice, and potato was probably derived from sloughed and damaged root cells, the major portion was from root exudates, as there was no discernable root debris in sterile hydroponic cultures. Moreover, no toxin was detected from cotton, canola, or tobacco in soil, again indicating that any damage to roots was a minor source of the toxins.

**Effects of Toxins on Worms, Nematodes, and Microbes**

There were no significant differences in mortality and weight of earthworms (Lumbricus terrestris) after 40 days in soil planted with Bt or non-Bt corn or not planted and after 45 days in soil amended with biomass of Bt or non-Bt corn or not amended.[13] Toxin was present in casts and guts of worms grown in Bt-contaminated soil, indicating again that toxin had bound on surface-active particles in soil, which protected it from biodegradation. When worms were transferred from Bt-containing soil to fresh soil, toxin was cleared from guts in 1–2 days. There were also no statistically significant differences in numbers of nematodes and culturable protozoa, bacteria (including actinomycetes), and fungi between rhizosphere soil of Bt and non-Bt corn or between soil amended with Bt or non-Bt biomass. Soil with biomass of Bt corn and from the rhizosphere of Bt corn was immunologically positive for toxin and lethal to larvae of M. sexta after 45 and 40 days, respectively. Although these results suggested that toxin released in root exudates of Bt corn or from degradation of biomass of Bt corn is not toxic to a variety of organisms in soil, only one species of earthworms and only culturable microorganisms and nema-todes were evaluated. More detailed studies, including techniques of molecular biology, are necessary to confirm the absence of effects of Cry1Ab and other Cry proteins on biodiversity in soil.

**Uptake by Plants of Cry Proteins from Soil**

When non-Bt corn, carrot, radish, and turnip were grown in nonsterile soil amended with Cry1Ab protein or biomass of Bt corn or in soil in which Bt corn had been grown, the toxin was not detected in any plants, whereas it was present in soil even after 180 days, the longest time evaluated.[14,15] No Cry1Ab protein was detected in non-Bt corn grown aseptically in hydroponic culture in which Bt corn had been grown aseptically, whereas it was easily
Persistence of bound toxins from Bt could pose a hazard to nontarget organisms and result in selection of resistant nontarget organisms, enhance selection of toxin-resistant target species, or enhance control of insect pests.

Movement of Cry Proteins in Soil

Cry1Ab protein added to the top of columns of soil was detected in leachates 1 and 3 hours after addition, with ca. 75% detected from soil not amended with clay and ca. 16% detected from soil amended to 12% with M or K; intermediate amounts were leached from soils amended to 3, 6, or 9% with the clays. Larvicidal activity was higher with leachates from soil not amended or amended to 3 or 6% than from soil amended to 9 or 12%. After 12 and 24 h, no protein was detected, indicating that it bound on the soils and desorption was reduced. Vertical distribution, in the columns, of protein not recovered in leachates confirmed that it moved less through soil amended with higher amounts of clay. Larvicidal activity of soil generally decreased with depth as clay concentration increased.

Cry1Ab protein was present in leachates from soil columns in which Bt corn hybrids of the three transformation events were grown, indicating some vertical movement from the rhizosphere. The protein was also present in leachates from soil amended three years earlier with Bt corn biomass, indicating that as the biomass degraded, toxin was released, and some bound on soil particles and some dissolved in and moved down with soil water.

Movement of Cry1Ab protein through soil was influenced by its tendency to stick on soil particles. The protein exhibited stronger binding and higher persistence in soils with higher clay concentrations—especially of M—and it remained near the soil surface, increasing the probability of it being transported to surface waters via erosion and runoff. In contrast, the protein was leached more through soils with lower clay concentrations, and may contaminate groundwater. Contamination of surface or groundwater, which depends greatly on the desorption of the protein and on the amount of water impacting soil as rain, irrigation, snow melts, etc., may pose a hazard to nontarget aquatic Lepidoptera, which are more plentiful in water than in soil. Without sufficient water, the protein will remain within the biologically-active root zone, where some protein, especially that not bound on particles, will be mineralized.

CONCLUSION

The interaction of larvicidal proteins with surface-active particles that differ greatly in composition and structure demonstrates the importance of such particles to the biology of natural habitats. These studies (summarized in Tables 1 and 2) also confirm and extend previous observations on the influence of surface-active particles on the activity, ecology, and population dynamics of microbes and viruses, as well as on the transfer of genetic information among bacteria in soil and other habitats.

Persistence of bound toxins from Bt could pose a hazard to nontarget organisms and result in selection of...
toxin-resistant target insects and thereby negate benefits of using a biological insecticide. However, persistence of bound toxins could also enhance control of target pests, particularly soil-borne ones. These aspects require more study, especially a case-by-case evaluation of each toxin.

These studies also indicate that caution must be exercised before the release to the environment of transgenic plants and animals that are genetically modified to function as “factories” (“biopharms”) for production of vaccines, hormones, antibodies, blood substitutes, toxins, and other pharmaceuticals. As with Bt plants, biomass of these plant factories will be incorporated into soil. Feces, urine, and even carcasses containing bioactive compounds from transgenic animals will also reach soil and other habitats. If these compounds (including prions from contaminated animal carcasses) bind on clays and humic substances, they may persist, and if they retain their bioactivity, they may affect the biology of these habitats. Consequently, before extensive use of such plant and animal factories, their persistence and the potential effects of their products on inhabitants of soil and other habitats must be evaluated.

INTRODUCTION

Late blight is a destructive disease found in nearly all areas of the world where potatoes are grown. Typical symptoms are water-soaked lesions on leaves that rapidly enlarge, resulting in dark, blighted areas and, eventually, in total destruction of the plant. Without chemical control and when cool and wet weather conditions prevail, late blight kills all plants in a field within 10–14 days. Extensive breeding efforts have failed to yield resistant cultivars satisfying the quality demanded by producers and consumers. The causal agent is Phytophthora infestans, a spore-producing, filamentous eukaryote classified as an oomycete. Oomycetes resemble fungi but have an independent evolutionary history. A recent worldwide displacement of the pathogen population caused a reemergence of late blight. Costs of losses and crop protection are estimated at US$3.25 billion per annum worldwide, ranking late blight as the number one disease in potatoes.

THE PATHOGEN P. INFESTANS

The first reports of late blight epidemics date from the 1840s when the disease devastated the foliage and tubers of potatoes in nearly all of Europe and the northeastern United States, and set the stage for the disaster recorded in history as the Irish potato famine. Ireland, at that time dependent on potato as the chief staple, lost nearly half of its population; over a million Irish starved to death and many more emigrated. This epidemic occurred prior to the development of the germ theory and, as a result, it was not until 1867 that Anton de Bary first demonstrated conclusively that a water mold, which he named P. infestans, was the causal agent of the disease—hence the official name P. infestans (Mont.) de Bary.¹ ²

More than a hundred years later, it became clear that Phytophthora is not a true fungus but instead belongs to a unique eukaryotic lineage, called oomycetes, that is evolutionarily unrelated to fungi. Features such as distinct cell wall compositions and metabolic pathways ³ partly explain the differences in sensitivity between fungi and oomycetes to certain classes of fungicides, and justify the introduction of the term “oomicides” as a generic name for drugs effective against oomycetes.⁴

Phytophthora (Greek for “plant destroyer”) is undoubtedly the best-studied oomycete genus because it encompasses species causing severe diseases on economically important crops such as soybeans, cocoa, and potatoes, and on valuable tree species such as Californian oaks, Australian jarrah trees, and European alder trees. Over 60 Phytophthora species have been identified and, regularly, new species are discovered. The host range of P. infestans is limited to the Solanaceae, with potato (Solanum tuberosum) and tomato (Lycopersicon esculentum) as the most prominent hosts.¹ ⁵ However, many species have a broad host range and thousands of plant species can be infected by Phytophthora.

THE DISEASE CYCLE

At the start of the growing season, spores may be produced from diseased potato sprouts arising from infected tubers. Well-known sources from where inoculum can easily develop and spread are cull piles or dumps, volunteer plants, and seed tubers. In addition, sexual spores, called oospores, can act as an inoculum source, but this is limited to areas where the two mating types that are required for completion of the sexual life cycle are present. Oospores are dormant structures that can survive in soil for many years in the absence of a host. When oospore germination is triggered, the germ tube develops into a sporangium, which can easily enter the infection cycle (Fig. 1C).

The disease spreads optimally under cool, moist conditions. Asexual spores, called sporangia, are dispersed by wind or in water drops. Infection generally occurs in the foliage and, occasionally, on stems (Fig. 2A). When sporangia land on a host, they either germinate directly or undergo cytoplasmic cleavage to form seven to eight swimming zoospores. Zoospores are attracted to the host where they halt, retract their flagella, and secrete materials to form a cell wall. This process is referred to as encystment. A sporangium or cyst germinates and the germ tube tip differentiates into an appressorium—a spherical or elliptical structure from which a penetration
peg emerges to breach the plant cuticle and the cell wall (Fig. 2B). After having passed the epidermis, the hyphae grow mainly intercellularly and form haustorium-like feeding structures that protrude into mesophyll cells (Fig. 2C). This biotrophic phase is an essential step in the disease cycle. In later stages, the pathogen adopts a necrotrophic lifestyle: it kills plant cells and feeds on dead tissues. Once in this phase, sporangia are formed on branched hyphae called sporangiophores, which emerge from the stomata and cover the lesion surface. Leaf symptoms consist of water-soaked, dark lesions that expand rapidly, resulting in total destruction of the plant in a few days (Fig. 1A). Individual lesions can produce 100,000–300,000 sporangia/day. In favorable weather, the period from infection to sporangia formation may be as short as 4 days; therefore, many generations of asexual spores can be formed and dispersed in one growing season, leading to late blight epidemics.

Tubers may be infected whenever sporangia and tubers come into contact. Infections can occur in both developing and mature tubers. Sporangia are washed from lesions on stems and foliage to the soil, and then through the soil to the tubers. They can survive for days or weeks in soil; therefore, tubers can still become infected for a period of time after lesions on the foliage are no longer producing sporangia. At first, infected tubers show dark blotches. The invasion proceeds into the outer layers of the tuber tissue, and the affected areas become firm and dry and somewhat sunken (dry rot) (Fig. 1B). The rot continues to develop after the tubers are harvested. Infected tubers are especially susceptible to secondary infections by fungi and bacteria, resulting in soft rot. During storage, soft rot can spread to previously healthy tubers.

Sexual reproduction only occurs when a leaf or a stem is invaded by two *P. infestans* strains, each with a different mating type. *P. infestans* is an outcrossing heterothallic species with two known mating types, A1 and A2. When the mycelium of an opposite mating type grows in the vicinity, specific hormones are produced, which trigger the formation of oogonia (♀) and antheridia (♂) on the opposite mating type. Subsequently, the nuclei in the gametangia undergo meiosis and, via a fertilization tube, a male haploid nucleus is deposited in the oogonium, which then develops into a thick-walled oospore (Fig. 3A). The nuclei fuse during the maturation of the oospore. When blighted potato plants decompose, numerous oospores are released (Fig. 3B) and are able to overwinter in the soil.

**POPULATION DISPLACEMENT AND REEMERGENCE OF LATE BLIGHT**

Central Mexico is considered to be the origin of *P. infestans* and the region where *Solanum* and *P. infestans* coevolved. Prior to 1980, the A1 mating type was distributed all over the world, whereas the A2 mating type was confined to Mexico. Mexican populations of the pathogen consist of many different genotypes and with a high variation in race structure. In contrast, one single genotype, designated US-1, populated the rest of the world, and all isolates seemed to belong to this clonal lineage. This situation changed in the 1980s when A2 mating type isolates were discovered in Europe. This was due to new migrations presumably initiated in 1976 by a large shipment of potatoes from Mexico to Europe. In the 1980s, these new and more diverse genotypes gradually migrated eastward to Eurasia and further to the Far East and Japan, resulting in a significant increase in the genetic variation and coexistence of the two mating types within populations. Sexual reproduction—and hence new recombinant types—may account for the observed increase in genetic variation and, indeed, occasionally oospores are detected in the field. Also in the United States and Canada, new genotypes that migrated from.
Mexico replaced the US-1 genotype. However, only a few clonal lineages settled successfully, and the genetic variation is much less diverse than in Europe. Overall, the new genotypes of *P. infestans* seem more aggressive than old US-1 isolates and, as a result, the epidemics have become more severe.[6]

**LATE BLIGHT CONTROL**

Integrated management practices are necessary to control late blight. Sanitary measures such as eliminating primary sources of inoculum, and cultural practices including early planting, can lower the chance of infections early in the growing season. In addition, continuous scouting for disease foci in potato fields is critical. In industrialized countries, regular spraying with agrochemicals is a common practice and keeps losses limited to about 15%. [7] The basic strategy is to prevent the establishment of any infection within the crop. For this purpose, fungicides with three types of activity can be used: those with protectant (contact) activity on the surface of leaves, those with penetrant (locally systemic) activity, and systemic fungicides. For the timing of applications, decision support systems (DSS) are used, giving recommendations based on the epidemiology of *P. infestans*, climatic conditions, infection pressure, and the costs and efficacy of crop protection measures.

A substantial contribution to late blight control would be the availability of resistant cultivars that also meet production and processing requirements. A continuing challenge for potato breeders is to combine resistance with commercial values in one potato cultivar. In the first half of the 20th century, late blight resistance derived from *Solanum demissum* and conferring resistance based on the gene-for-gene interaction were bred into *S. tuberosum*. Unfortunately, each of the 11 genes succumbed to attack by *P. infestans* within a few years, demonstrating the capacity of this pathogen to quickly circumvent recognition by its host. Breeding programs subsequently focused on quantitative resistance, often referred to as horizontal resistance, again without much success. In recent years, the idea that horizontal resistance and single gene resistance are truly distinct is being challenged, thus forcing a resetting of breeding strategies.[8] Currently, a wide variety of wild *Solanum* species are being explored.
for novel resistance genes, and there is a strong tendency toward \( R \) gene “pyramiding.” Recently, the first two late blight resistance genes were cloned. \( R1 \) is derived from \( S. \) demissum and confers resistance to strains carrying the avirulence gene \( Avr1 \). The other gene \( Rpi-blb \) is from \( Solanum bulbocastanum \) and is thought to confer resistance to a much broader range of strains.\(^7\) They both belong to the NBS-LRR class of resistance genes—a large super family effective against a wide variety of pathogens.\(^9\) Deploying resistance genes using
a genetically modified organism (GMO) approach may bring us closer to the resistant potato cultivar with the desired characteristics.

CONCLUSION

Every strategy to develop a durable solution for the late blight problem, either by crop protection or via resistant cultivars, should consider the role of both the pathogen and the host. In recent years, large genomics resources have been developed for potato and P. infestans, and the challenge for the near future is to explore and exploit these resources to unravel infection strategies of the pathogen and resistance mechanisms that can defeat the pathogen. This knowledge would help establish a more rational design of oomicides and more strategic breeding programs. However, for the time being, growers will have to cope with this devastating pathogen.

Leaf Cuticle

Gwyn A. Beattie
Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

The leaf cuticle is the waxy layer that covers the surface of leaves. Its main function is to protect the plant against water loss, and it is therefore critical to life in an aerial environment. It offers protection against environmental stresses as well as microbial pathogens and herbivorous insects, and contributes to the ability of many plant species to keep their leaves clean. These functions are related to the structure and composition of the cuticle, and particularly its main functional component, the cuticular and epicuticular waxes.

THE STRUCTURE AND FUNCTION OF LEAF CUTICLES

The thin continuous layer known as the cuticle is present on the epidermal cell surfaces of leaves, including on the trichomes and guard cells, as well as on the cells lining the substomatal cavities. This nearly impermeable membrane was likely a key development during the evolution of plants from aquatic to terrestrial habitats.[1] Plant cuticles consist of a network of insoluble structural polymers, typically cutin, that is infused with a complex mixture of lipids, or cuticular waxes.[2] These waxes are usually very long-chain fatty acids and their oxygenated derivatives, including alcohols, aldehydes, ketones, and esters. In contrast to cellular lipids, which are usually 15 to 18 carbons in length, cuticular waxes are usually much longer, often 20 to 40 carbons in length. Some of the waxes are extruded onto the surface of the cutin layer (Fig. 1). These epicuticular waxes form a relatively smooth layer on some plant surfaces, and on others they form crystals (Fig. 2). Epicuticular wax crystals vary greatly across plant species in their morphology and distribution.[1,3]

A major function of the leaf cuticle is to serve as a diffusion barrier; it minimizes the loss of water and solutes while also limiting the inward movement of aqueous pollutants. The leaf cuticle can reflect light, particularly when crystalline epicuticular waxes are present, and this provides protection against both damaging UV radiation and light-driven temperature increases and their consequent reductions in transpiration, thus improving water conservation.[3] The presence of crystalline epicuticular waxes can confer water repellency. Water applied to the surface of water-repellent leaves forms droplets that roll off, and these droplets collect nonadhering contaminating particles such as dust and microbes, thus effectively cleaning the leaf surface.[4] Water repellency is particularly common to the adaxial surfaces of many plant leaves, where it may help prevent the formation of water films over the stomata in humid environments. Low leaf wettability resulting from the hydrophobic waxes—particularly crystalline waxes—contributes to a small contact area between aqueous solutions and the leaf surface. This is likely of great importance to photosynthetic gas exchange and thus plant growth, to the ecology of the leaf-associated microflora (including the potential infectivity of pathogens), and to the retention and uptake of aqueous pollutants and agricultural sprays such as pesticides, herbicides, and plant growth regulators.[3,5]

FACTORS INFLUENCING LEAF CUTICLES

The quantity, composition, and structure of the cuticular waxes are specific to the plant species, the plant age, and even the adaxial versus abaxial leaf surface. For example, as leaves age, crystalline waxes appear to be degraded and this changes the surface characteristics and topography of the leaf. Environmental conditions that affect the waxes include light intensity, UV-B exposure, water stress and temperature.[3] For example, plants grown under elevated light intensity or drought stress often produce more, or different, cuticular waxes than nonstressed plants. Wind can disrupt or remove the waxes by rubbing, flexing, or particle impaction, and also has been suggested to melt the waxes due to frictional heat. Rain can remove epicuticular waxes from the leaves (as illustrated by the presence of crystalline waxes in rain drops after they impact the leaf surface) and can alter wax composition by selectively removing certain classes of crystals. Air pollutants and acid rain can cause structural degradation of the waxes, stomatal occlusions, and shifts in wax composition, as has been well documented with conifer needles. In fact, wax
degradation and compositional shifts have been used as bioindicators of air pollution in forests.\textsuperscript{[3]}

**LEAF CUTICLES AS PLAYING FIELDS FOR INSECT HERBIVORES AND THEIR PREDATORS**

Leaf–insect interactions are dominated by the cuticle as an obstacle to insect attachment and movement.\textsuperscript{[6]} Cuticular waxes interfere with attachment and movement of insects primarily by exfoliation of the wax crystals. In fact, carnivorous pitcher plants have capitalized on wax exfoliation. (The pitcher plant captures insects by producing wax plates that are readily released upon contact by an insect.) This exfoliation can deter insect herbivores, thus providing defense against herbivory, but may also deter the predators of these herbivores. Among the many diverse surfaces that support insects, leaves with crystalline waxes are unusual in the effectiveness with which they prevent insect adherence.

The chemical and physical properties of leaf cuticles influence host plant selection by herbivorous insects.\textsuperscript{[6]}

For example, the crystalline waxes can dictate the appearance of leaves, often giving them a whitish color, which affects their attractiveness to some herbivorous insects. Similarly, specific waxes can influence the acceptance or rejection of a potential plant host for feeding or for the deposition of eggs, which often requires selection of a host that is suitable for larval development. Insect behavior may be affected by the ability of cuticular waxes to serve as solvents for insect pheromones or other volatile compounds from the environment; however, this area has been relatively understudied considering its potential ecological significance.

**INTERACTIONS BETWEEN LEAF CUTICLES AND THE LEAF MICROFLORA**

The leaf cuticle influences the immigration of waterborne and airborne microbes by affecting water repellency and the formation of a still-air boundary layer surrounding the leaf. The cuticle also affects the attachment of some bacteria, yeasts, and fungi to leaves, as illustrated by the finding that leaf surface hydrophobicity...
promotes attachment by many fungal spores. Similarly, although not well characterized, the cuticle can influence the size of the resident bacterial and yeast populations, an influence that may be mediated, to a large degree, by leaf cuticle–water relations.\(^5\) A few recent studies suggest that bacteria may have mechanisms for penetrating plant cuticles;\(^5\) however, bacteria are generally regarded as unable to penetrate intact cuticles. This is supported by the finding that bacterial production of known cuticle-degrading enzymes—namely cutinases—is a rare trait, and by knowledge that phytopathogenic bacteria invade leaves via natural openings, wounds, and insect damage, but not via direct penetration. In contrast, phytopathogenic fungi have evolved multiple mechanisms for penetrating plant cuticles, and clearly respond to distinct cuticle-dependent signals.\(^7\) Spores and germings of phytopathogenic fungi are often associated with visible erosion of the cuticle, which likely results from enzymatic degradation. Cutin-degrading enzymes have been characterized in many fungal species, although wax-degrading enzymes have not been identified. Some fungal species penetrate leaves without producing highly developed infection structures, whereas others produce appressoria (structures that aid penetration). These structures often employ turgor pressure as a mechanism of force. Simple contact with a surface—particularly a hydrophobic surface—induces appressorium formation as well as adhesion and germination in some fungi. For example, upon contact with the leaf cuticle, *Erysiphe graminis* secretes a liquid that aids adherence and creates a localized hydrophilic region, presumably by degrading cutin, and the resulting hydrophilicity stimulates germination. Similar to their effect on insects, specific cuticular waxes can act as stimulants or deterrents of specific fungal behaviors, including germination and appressorium formation.

**CONCLUSION**

Current research interests in leaf cuticles—particularly in cuticular waxes—include their diversity and biosynthesis; their role in plant evolution and development; their role in plant responses to insects and microbes, as discussed here, as well as to drought, freezing temperatures, solar radiation, and air pollution; their role in the retention and penetration of agricultural sprays; their use as industrial plant waxes; their use in breeding of ornamental and agronomic plants with improved performance; and their contribution to atmosphere aerosols.\(^8\) Mutants that are altered in loci involved in the biosynthesis, secretion, and regulation of cuticular wax production have been identified for several plant species. The cloning and characterization of these and other loci involved in cuticle synthesis and regulation, along with current tools in plant molecular biology, should benefit these research areas by increasing our fundamental understanding of cuticle formation and regulation and by providing information useful for cuticle modification, such as for crop improvement.

INTRODUCTION

Leaves are constructed mechanically and biochemically primarily for their function in photosynthesis. They must be constructed at low metabolic cost and protect themselves against mechanical stresses, climatic extremes, excess light, and damage by herbivores and pathogens. Concurrently, they must balance water use efficiently. Some leaves are specialized for additional functions such as support of the whole plant or storage. The leaf surface, parenchyma, and vascular system show unique contributions to each of these functions. The overall size and shape of leaves are also relevant for construction cost, energy transfer, light interception, and mechanical properties. The development of each leaf and its functions, from inception to death, is subject to a number of controls. These respond to the environment (nutrition, water and solute status, etc.) in ways that are often manifestly adaptive. Leaf traits exist in very diverse combinations in response to natural selection on the net benefit of a leaf in all its functions. Artificial selection imposes different weightings of traits; the optimal combinations in agriculture are in some cases quite divergent from wild types, as in leaf area per mass and geometry of leaf display.

PERFORMING PHOTOSYNTHESIS

The primary function of a leaf is photosynthesis. Leaves are typically thin, providing maximum surface area for light interception at the lowest cost in metabolites and nutrients. Nonetheless, leaves are diverse in thickness, size, shape, reflectivity and other optical properties, and presence of trichomes. The diversity reflects demands to 1) use all resources—not just light—efficiently (particularly water and nitrogen and sometimes other nutrients), and not just for photosynthesis but also for defense;[1] and 2) avoid damage, both biotic (from herbivores, fungi, etc.) and abiotic (from wind, extreme temperatures, ultraviolet radiation, acute shortage of water, etc.).

STRUCTURE OF THE LEAF

The leaf surface is covered by a cuticle (Fig. 1). This hydrophobic layer limits losses of water and ions, offers the first defense against pathogens, and conditions the optical properties of the leaf. When thick and scalelike, it reduces light interception as a protection against photoinhibition and thermal loading. The outermost layer of cells is the epidermis. This layer provides some structural strength and significant ultraviolet screening via absorptive chemicals. A small percentage of epidermal cells is specialized as guard cells, forming the stomata that regulate the exchange of gases, primarily CO₂ and water vapor but also leaf volatiles such as terpenes and a portion of the O₂. Other specialized cells (trichomes) may be present, presenting long hairs that have many functions—defense, radiative balance, control of surface wetting, etc.

The largest volume of cells is parenchyma cells specialized for photosynthesis. Palisade cells are columnar and strongly photosynthetic. Spongy mesophyll cells are also photosynthetic, while offering air passages for gas exchange. Complete photosynthesis (both the capture of light to produce reductant and carbon fixation) is present in all these cells in most plants. In plants with the C₄ pathway, the parenchyma cells other than the bundle sheath capture CO₂ in a transportable form (such as malate) and generate reductant. Final sugar generation occurs inside the bundle sheath, which is poorly gas-permeable, allowing high partial pressures of CO₂ to build up.

Photosynthetic cells typically have thin cell walls for high conductivity to dissolved gases. Stress-tolerant plants—the sclerophylls—toughen their leaves with secondary cell wall growth, plus dense packing; consequently, they have low photosynthetic rates. Other structural features of the leaf interior include sclereids (as in sclerophylls) and, in grasses, silica bodies (whose evolution may even have caused some herbivore extinction[2]). Some leaves contain laticifers, fused cells that transport quantities of insect-detering latex.

Veins are a major leaf structure. The xylem imports water, of which usually more than 99% is used over the life of the plant for transpiration as opposed to for new
growth. The xylem also imports some nutrients. It may be strongly lignified; this condition, plus the vascular geometry as branched cylinders, is the dominant contribution to biomechanical integrity. Leaves must be strong (resisting high forces of gravitational loads, winds, and herbivore action), stiff (resisting bending, to maintain light capture), tough (requiring much work to break them), and resistant to crack propagation.[3] Phloem is the other major vascular component. It transports photosynthesized sugars out of mature leaves. It also transports hormones, some photosynthetically reduced nutrients (N and S compounds), and nutrients that recycle as signals to regulate root activity. The phloem possesses some parenchyma cells, some fibers, and sclereids as lesser contributors to structure and defense. The vascular bundles of xylem and phloem occur commonly in nets or, in monocots and ginkgos, as parallel strands. The pattern is in part adaptive (e.g., grasses withstand grazing by regrowth from the base, easiest biomechanically with parallel veins) and is in part an evolutionary constraint. In C₄ plants, mesophyll and bundle-sheath cells cluster tightly around xylem and phloem in the Kranz anatomy, which enables concentration of CO₂ for efficient photosynthesis.

A number of variations occur in internal structure. Thick mesophyll of high water content stores water in succulent species. In those species performing CAM photosynthesis, this also serves as inexpensive, copious storage for malate, reducing the limit on growth rate.

LEAF MORPHOLOGY

The leaf proper commonly has a petiole, supporting it away from the stem and other leaves. The petiole, although minimally photosynthetic has a significant fraction of total leaf mass; minimization of this mass is often important in carbon gain per mass and growth rate.

Overall shapes of leaves and their arrangement on the stem are usually diagnostic of a species or an ecotype; occasionally the shape is plastic, as in sassafras (lobing) and aquatic plants (long, thin water leaves contrast with aerial leaves). Leaf types divide fundamentally into simple and compound (Fig. 2). Compound leaves appear to cost less energy to construct but are less durable.[4] Other geometric features include entirety (no reentrant curves) vs. dissection into discrete lobes. Dissection increases the boundary layer conductance for gases and heat;[5] dissected leaves remain closer to air temperature than do entire leaves. Another marked division is between flat leaves and the needle-shaped leaves of conifers (most rushes and sedges have tiny leaves but photosynthetic stems). Needle leaves have low photosynthetic area per unit mass but possess strength and damage-resistance.

Leaf size also varies among species, and is more plastic than is geometric shape within a species. Thick leaves have low area per mass (i.e., per specific leaf area). All else being equal, thickness confers high photosynthetic capacity per area but correlates with smaller leaf area. The
The net effect on photosynthesis per mass—the most important correlate of relative growth rate—is nearly neutral.\[^{[6]}\] Thinness, however, is correlated with higher N content that raises photosynthesis per unit mass, and offers greater shading of competitors. The lower structural content makes such leaves more damage-prone; they are typically short-lived and never evergreen. Leaves of an individual plant can acclimate in thickness. Leaves receiving more sunlight develop higher photosynthetic capacity, commonly from larger cells and more layers. Higher photosynthetic capacity relative to stomatal conductance can also confer higher water-use efficiency by virtue of a lower operating point in leaf-internal CO\(_2\).

**CONTROLS OVER DEVELOPMENT AND DEATH**

Leaves vary widely in development rate and lifespan. Initiation has numerous controls, both intrinsic and environmental. Leaf expansion (initiation time and duration) is paced to thermal time in degree-days, which has been shown to have a molecular basis in cyclin proteins.\[^{[7]}\] Cell division and cell enlargement are restricted to rather fixed intervals; adverse conditions during early expansion (low light, dryness of air or soil) permanently eliminate some growth potential, which shows up later as smaller leaves.\[^{[7]}\] Leaf thickness and attendant photosynthetic capacity responds as well to temperature and irradiance during expansion. Patterns are apparently adaptive, as in making leaves of greater protein content at low temperature, largely compensating for lower activity per unit mass of protein.

Leaves lose function gradually from causes such as UV damage and abruptly from causes such as salt accumulation.\[^{[8]}\] Ultimately, even in the absence of lethal insults such as pathogens or frost, a leaf's death is programmed by internal and environmental signals (e.g., by the photoperiod as a reliable signal of the end of frost-free or drought-free days). Leaves thus can be evergreen or deciduous in response to drought or photoperiod. Leaf death is an orderly process. An abscission zone forms at the base, and typically half of the nutrients are scavenged, to be stored or used in newer leaves. Limits to the fraction scavenged are set by the need to maintain export functions.

**ADDITIONAL MODES OF STRESS PROTECTION AND SPECIALIZATION**

Leaves withstand wind stresses by drag reduction as well as by simple strength and toughness. The lamina must bend and fold properly, requiring specialized shapes.\[^{[3]}\] Excess light or heat loading induces in selected species (e.g., grasses, legumes) alterations of leaf shape (e.g., rolling) and gross orientation (heliotropism). These changes complement the protection offered by reflective cuticles and pubescence. Tolerance of trampling in grasses is conferred in part by flexible and readily repaired vasculature. Leaves have other structures ancillary to photosynthesis but important nonetheless. These include salt glands for ion balance, trichomes, or hairs for physical and chemical defense.

Pathogens are deterred by many defenses, including cuticular integrity, chemical composition, and stomatal design. Drip tips in the wet tropics reduce wetness duration and thus fungal challenges. Herbivory by insects and vertebrates is deterred chemically and structurally, as noted earlier. Leaves of sclerophylls are tough and thick primarily for such defense during their long lifetimes; inelasticity is no particular advantage for handling turgor pressure changes in water stress.

Some leaves are modified for functions remote from photosynthesis. Some tendrils—which provide support for the whole plant—are modified leaves, as in the garden pea. Bulbs incorporate thick leaves modified for food storage; the petioles of celery function similarly. Leaves
may be modified into spines for protection. Leaves may trap and digest insects, as in pitcher plants, sundews, and flytraps. These modifications are almost always an adaptation to low nutrient availability in soil.

**TRAIT SELECTION AND THE NET VALUE OF A LEAF**

What do these diverse leaf designs achieve under the diversity of growing conditions? One can estimate costs of constructing and maintaining a leaf in operation as well as current and lifelong-integrated benefits. A sine qua non for survival—much less for productivity—is that a leaf must pay back its own construction costs in photosynthate. This constrains the design lifetime, the nutrient content, and other features. Leaves must also be efficient in using scarce resources such as N and water. Conifers and sclerophylls appear to be selected for this. A conifer may have a low photosynthetic rate (1/4 that of a forb), but may maintain this rate over longer times (threefold) with less N (half as much). The conifer’s N-use efficiency is 

\[
\left(\frac{3}{4}\right)/\left(\frac{1}{2}\right) = 1.5\text{-fold greater than the forb’s.}
\]

A great many traits—structural, biochemical, and phenological—are thus under selection. Crop plants retain many traits and trait combinations selected under predomestication natural conditions. Artificial selection goals now conflict with fitness criteria of old; this conflict is important to understand in breeding improved crops. An example is breeding for plants with erect leaves that share light interception well with other plants of the same stand; this design consciously forgoes competitor shading. In this task, it is well to consider that selection is diluted among many traits, such that many tradeoffs in structure (as in specific leaf area) currently operate near neutrality; performance is nearly insensitive to variations near the current mean. Extreme events may be most important in selection. These are rarely monitored or quantified in importance in current breeding or crop ecology.

Leaf Surface Sugars

Johan H. J. Leveau
Netherlands Institute of Ecology (NIOO-KNAW), Heteren, The Netherlands

INTRODUCTION

Plant leaves attract a wide variety of organisms. For most of them, the appeal lies in the fact that the leaf is the primary site of photosynthesis, and thus represents an abundant source of carbohydrates such as glucose, fructose, and sucrose, as well as oligosaccharides (e.g., raffinose, stachyose, and verbascose) and sugar alcohols (e.g., mannitol and sorbitol). The waxy cuticle that covers the leaf effectively confines these compounds to the leaf’s interior, but it cannot entirely prevent small amounts from finding their way to the outside. Furthermore, it offers only minimal protection against the attacks of herbivorous insects, by which substantial amounts of leaf sap can reach the leaf surface. Some plants actually invite the visitation of insects and other organisms by the release of highly localized puddles of sugar on their leaf surfaces. In this regard, the leaf surface, or phyllosphere, functions as an interface where sugars serve different purposes to the plant and to its visitors.

The first part of this article lists the shapes and abundances in which sugars can be found on the surfaces of plant leaves. In the second part, the fates and relevance of leaf surface sugars are discussed.

SOURCES OF LEAF SURFACE SUGARS

Leachates

Leaching is defined as the process by which organic and inorganic metabolites are lost from above-ground plant parts by leakage from the leaf interior. It is considered a passive and reversible process that is driven by the difference in metabolite concentrations across the leaf cuticle, i.e., between the inside of the leaf and the leaf surface. When there is water present on the leaf, for example, as drops of rain or dew, leaching to the surface is greatly stimulated, probably because the water acts as an effective sink for the leachates.

The most common method for assessing the occurrence and abundance of leachates is by repetitious rinsing of the leaf surface, usually with water. Such leaf washings contain an impressive collection of inorganic and organic substances. The bulk of leachates consist of sugars, with fructose, sucrose, and glucose being most predominant. Usually, leachates are not found in very great abundance. For example, only about 2.5 μg of fructose, glucose, and sucrose can be washed off a greenhouse-grown bean plant leaf. A leaf like this contains between 1 and 5 mg sugars on the inside, so that losses due to leaching account for only 0.05 to 0.25%. While such amounts may appear small on a per-leaf basis, they are quite impressive on a larger scale. One report details the loss of 800 pounds of carbohydrates per year per acre from an apple tree orchard as a result of leaching.

There are numerous factors that influence the rate by which sugars are leached to the leaf surface; Tukey provides a comprehensive list. One is the wettability of the leaf, which is often directly related to its waxiness. Leaves of pea, orange, and sugar beet are wetted with more difficulty than those of bean, squash, banana, cacao, and coffee, and hence are less susceptible to leaching. Leaf surface structures such as hairs and veins can hold water by capillary action and may in that way enhance leaching. Other important factors are the time, intensity, and amount of rain, mist, or dew that a plant is exposed to. In rainwater, for example, sugar concentrations have been measured in the range of tens of milligrams per liter, whereas in dew, which is more stagnant, they were 10 times higher. A continuous light drizzle increases leaching more than the same amount of water in a short, heavy rain. This may be explained partly by the increased runoff from leaves during heavy rain.

Extrafloral Nectaries

Extrafloral nectaries are secretory glands on leaves and stems of plants. They produce a liquid with nectarlike qualities, and they have been found on plants from over 1000 species. An extrafloral nectary can appear nonstructural, as a modified stipule, or as modified trichomes on the margins or surfaces of a leaf. Extrafloral nectaries secrete the sugars glucose, fructose, and sucrose, along with smaller amounts of protein and inorganics. The source of the sugars is the phloem, which often—but not always—ends near the nectary. Extrafloral nectar tends to be sweeter than phloem sap, in part because it is exposed to the air, and therefore more prone to evaporation. Extrafloral nectaries of broad bean (Vicia faba) secrete a nectar that can contain...
several hundreds of micrograms of sugar per μl. Leaves of the castor bean (*Ricinus communis*) produce an average of about 2 microliters of nectar per day, consisting of 75% sugars (sucrose, glucose, and fructose).

**Guttation Fluid**

Guttation is caused when the transpiration from a leaf is so low that the hydrostatic pressure in the xylem is able to force apoplastic fluid out to the leaf surface. This occurs in the early morning or late evening when humidity is high, temperature is low, and soil moisture is abundant. Guttation fluid follows the path of least resistance, and usually comes out of modified stomata called hydathodes. Depending on the plant species, hydathodes are located at the tips or margins of leaves, or on the leaf surface. Guttation fluids contain relatively low concentrations of sugar, usually anywhere from less than 1 μg per liter up to nearly 40 μg per liter. Guttation fluids from rye, wheat, and barley seedlings contain mostly glucose and galactose. A secondary effect of guttation fluids is leaf injury caused by an accumulation of salts when guttation droplets on the leaf surface evaporate.

**Manna**

Manna is a sugary substance that is excreted from leaves and stems of certain trees and eucalypts (*Eucalyptus* and *Angophora* species). It exudes after injury from incisions or from feeding by insects such as the gum tree bug (*Amorbus obscuricornus*). The exudate crystalizes and forms white beads that oftentimes fall to the ground. Manna generally consists of 60% sugars, most of which is raffinose, a trisaccharide of fructose, glucose, and galactose, with smaller amounts of other sugars such as melibiose (a disaccharide of glucose and galactose), sucrose, glucose, fructose, and stachyose (a tetrasaccharide of fructose, glucose, and two units of galactose). A major component of the manna from the ash tree (*Fraxinus ornus*) is the sugar alcohol mannitol, also called mannate or manna sugar. Manna may resemble phloem sap in sugar composition, but the proportional abundances of individual sugars can be markedly different, which in part may be due to the presence of sugar-specific enzymes such as sucrases and oxidases in the saliva of the feeding insect. Manna is oftentimes confused with other insect-mediated sources of leaf surface sugar. For instance, one hypothesis for the biblical reference to manna points to honeydew (see below).

**Honeydew**

Honeydew is the sugary excretion of nymphal stages of aphids, coccids, and insects belonging to the family *Psyllidae* (plant lice). These phloem feeders insert their stylets into the plant leaf and take advantage of the positive pressure of the phloem for the collection of leaf sap. Because phloem is high in sugars but low in nitrogen, the insect must ingest large amounts of phloem to meet its nitrogen demands. The excess phloem sugars pass through the gut of the insect and are excreted as waste. This honeydew is ejected with force from the end of the insect’s abdomen, which prevents the insects from sticking to one another and to the leaf surface. Honeydew contains about one-third sugars, most of which are small polysaccharides with additional glucose, fructose, and sucrose. Other sugars such as melezitose, erlose, raffinose, and trehalose have been found in the honeydew of some sapfeeders. These sugars are synthesized from plant-derived sugars during passage through the insect gut, and they are thought to help the sapfeeder keep its osmotic balance while feeding.

**Lerp**

Lerp is a waxy material secreted as a protective scale by psyllids such as the lerp psyllid (*Glycaspis brimblecombei*). A lerp (the Australian Aborigine word for house) is a small conical structure under which the larva feeds and grows to adulthood. It is made by the larva itself from excreted honeydew, and is composed for 90% of glucose polymers.

**Pollen and Fungal Spores**

Pollen consists of up to 10% carbohydrates (dry weight), including starch and soluble sugars (fructose, glucose, sucrose). It is also a good source of protein and lipids. The diameter of a pollen grain is about 15–50 μm, which makes it highly motile in the wind. High concentrations of up to thousands of grains per square centimeter can easily be found deposited on leaf surfaces. The pollen can also be readily washed from leaves again, for example, by rain. Wind and rain also help disperse fungal spores that can be covered with a gelatinous coat containing considerable amounts of sugar.

**FATES AND RELEVANCE OF LEAF SURFACE SUGARS**

**Food**

Many organisms rely on plant leaf sugars for nutrition. For some, it is their main source of carbohydrates; for others, an occasional delicacy. Native Americans reportedly collected honeydew and ate it as candy. In Turkey, Iran, and Iraq honeydew is harvested from branches
infested by aphids by shaking or beating the honeydew off. It is then dissolved in water, strained, mixed with eggs, almonds and spices, and sold as a popular sweet. Aboriginal Australians ate lerp as a staple food, and they prepared manna from the leaves of the eucalyptus tree.

Manna, honeydew, and lerp are also common food sources for a variety of bird species. Their high carbohydrate content makes them very attractive sources of energy. Many of these birds have to supplement this diet by feeding on insects to meet their protein requirements. Many species of ants are readily attracted to the sugar in extrafloral nectaries, honeydew, and manna as sources of carbohydrates. Forest- or leaf-honey is produced by bees from the honeydew of certain aphids and various other insects.

Microbes that visit or inhabit leaf surfaces have quantity requirements for sugars that are very different from those of humans, birds, or insects. For example, while a human may crave 300 grams of carbohydrates per day just for maintenance, a bacterium is able to replicate itself with $10^{15}$ times less, or a mere 0.3 picograms of glucose. Obviously then, the tiny amounts of sugars that are found in leachates and guttation fluids are most relevant to such bacteria because they are sufficient to allow the generation of a substantial population size on plant leaves. For example, 3 micrograms of leached sugar could and often does produce 10 million bacterial cells on a single bean leaf under environmentally favorable conditions.

For many bacteria that have made the plant leaf surface their preferred habitat, sugars appear to be the limiting factor for growth. Not unexpectedly, many of these bacteria have adopted ways to gain access to more of the sweet stuff. One is the ability to lower the surface tension of water, thereby, for example, making rain drops on the leaf surface flatter so that the efficiency of leaching is increased as a result of the larger surface area. Another bacterial adaptation is the ability to synthesize the plant hormone auxin, which is thought to trick the plant into the release of nutrients, including sugars. Because sugars are often a limiting factor in bacterial growth, they can evoke fierce competition. Such competition is the basis for many of the strategies for the biological control of microbial plant pests.

Redistribution and Removal of Sugars from the Leaf Surface

Water that moves freely across the leaf surface is able to redistribute sugars and wash them off the leaf surface. These washed-off nutrients can land on lower leaves, where they can be taken up again by the plant, or on the ground below, where they can be used by the root system or other organisms. Such leachates may contain considerable amounts of nutrients; in one experiment, bean plants were grown through one complete generation on the leachates from squash leaves.

Carriers of Information

Some organisms rely on leaf surface sugars as carriers of information during their interaction with the plant and with other organisms. For example, when choosing a spot to lay her eggs, a female of the European corn borer butterfly (Ostrinia nubilalis) relies on the surface sugars fructose, sucrose, and glucose to assess the carbohydrate content of the leaf. Extrafloral nectaries attract ants, which in turn protect the plant by removing herbivorous insects. Parasitic wasps and flies use these extrafloral nectaries as meeting places for mates. Some plants have ways to control the amount, composition, and viscosity of this nectar and are able to selectively attract or deter protectors or herbivores. The mutualistic interaction between aphids and ants is based on the attraction of ants to the honeydew. For the aphid, removal of the sugary compound prevents itself and the leaf surface from becoming too sticky. Aphids also can choose their mutualists and antagonists by making the honeydew selectively attractive through the synthesis of honeydew-specific sugars, such as melezitose or erlose.

CONCLUSION

Because of its exposed character, the leaf is subject to many physical, chemical and biological influences that greatly affect the form and quantities of sugars found on its surface. This makes the leaf a highly dynamic and heterogeneous environment, for which the ecological role of sugars and changes in their abundance is not always easy to interpret or predict. This holds true in particular for microbial visitors to the leaf surface. For the most part this is due to the wholly different scale at which these microbes experience the leaf surface and its sugars. Because their carbohydrate requirements are so small, even small changes in sugar availability can have tremendous consequences. Furthermore, spatial variation in sugar availability is much more pronounced on the micrometer scale at which these microbes live. Only recently a successful attempt was made to follow the sugar consumption of individual bacteria in the phyllosphere. From this study and more to come, an understanding will emerge that will enhance our appreciation for the role of sugars in microbial colonization of the leaf surface, and which could well help to improve current methods for biological control of plant pests.

Cindy E. Morris
Institut National de la Recherche Agronomique, Montfavet, France

INTRODUCTION
The phyllosphere supports the growth of a diverse flora of bacteria and fungi; however, as a habitat for microbes, the phyllosphere presents a stressful environment that is strongly influenced by physical factors. Phyllosphere microbial residents grow through the utilization of the limited resources available in this habitat; survival is also predicated upon the ability of organisms to cope with the varied environmental stress conditions including fluctuating water availability, heat, osmotic stress, and exposure to solar UV radiation (UVR).

PHYSICAL NATURE OF THE LEAF SURFACE
Leaves are surrounded by a boundary layer of air that can influence temperature, relative humidity, and concentrations of gases and volatile metabolites relative to that of the ambient air. Within the leaf boundary layer, temperature can be as much as 4–7°C different (generally greater) from that of the air and RH as much as 20% above ambient conditions. Humidity effects, especially the increased RH within thick closed canopies, tend to favor the epidemic development of some plant pathogens. Modification of the canopy environment of a crop, if possible, can affect disease incidence. For example, closed-canopy cultivars of bean are more susceptible to white mold than open-canopy cultivars. The epidermal cells of leaves are covered by a cuticle. Cuticles are significant barriers to the diffusion of water-soluble compounds from the leaf apoplast toward the surface of the leaf and thereby probably foster oligotrophic conditions on leaf surfaces. Cuticles also influence the hydrophobicity of leaves, the reflectance of light, and leaf cooling. Leaf surfaces have topographical features such as leaf hairs, glandular trichomes, stomata, junctions of epidermal cells, hydathodes, and grooves over leaf veins, some of which are associated with thinner cuticles and boundary layers or may facilitate local accumulation of water. Terrestrial plants experience incessant fluctuations in the quantity of free water present on their leaves. Condensation and impaction of water droplets on leaf surfaces alternate with evaporation and runoff of water in cycles that are generally diurnal. The ebb and flow of free water in the phyllosphere lead to variations in local pH, as substances such as ammonia, sulfur dioxide, and calcium carbonate that may be present on leaf surfaces are dissolved, and also lead to variation in local concentrations of leaf surface nutrients.

SOLAR ULTRAVIOLET RADIATION
Leaf size, angle, and the density of plant canopies can markedly reduce UVR penetration to lower leaves; conversely, the relative humidity and free surface moisture within lower areas of dense canopies is typically maintained at higher levels. The abaxial (upper) surface of completely exposed leaves is one of the most light-intense of the terrestrial microbial habitats. Several reports have shown that microbial populations tend to be larger on adaxial surfaces, although some fungal species can survive equally well on abaxial surfaces. UVR filtering by leaves higher in the canopy can modulate microbial populations on lower leaves. The UVR-sensitive fungal plant pathogen Exobasidium vexans colonizes and incites disease symptoms on lower leaves of its tea host, and the fungus is otherwise highly sensitive to solar UVB radiation. Solar UVR affects microbial populations on a daily basis; however, long-term seasonal effects, although evident, are more difficult to discern because of the confounding effects of temperature and desiccation.
PLANT CANOPY EFFECTS

Plant canopies affect plant disease epidemiology, particularly in the rain-splash dispersal of fungal spores. Understanding the physics of rain splash and impacting droplets has been important to modeling studies of spore dislodging and movement.\[10\] Drop size plays a major role in the overall splash process.\[11\] Canopy effects include secondary movement of raindrops; “drip” drops, or secondary drops falling from leaves, travel at reduced speeds and play a reduced role in spore dispersal. Thus, thicker canopies tend to reduce spore dispersal possibly due to decrease in spore removal by drip drops or because fewer raindrops reach impaction sites, and by direct interception of spore-carrying droplets by intervening plant surfaces prior to spore “escape.”\[12\] However, it should be noted that thicker canopies can have a positive effect on spore germination by lengthening the duration of leaf wetness. The momentum of rain is important in stimulating the growth of the plant-pathogenic bacterium *Pseudomonas syringae* in the bean phyllosphere.\[13\] Although the effect of plant canopy or canopy position is not known for this example, it is intriguing that the ecology of both plant pathogenic bacteria and fungi can be strongly influenced by rain, the effect of which is markedly conditioned by the canopy micro- and macroenvironment.

Leaves are also exposed to exogenous compounds that may be deleterious to bacteria. These include pesticides, the major air pollutants originating from the combustion of fossil fuels and from intensive agricultural practices, and heavy metals from smelting factories.\[10\] Exposure of leaves to agricultural chemicals utilized for pest or pathogen control is another area influenced by plant canopies. In these cases, uniform pesticide distribution is the desired outcome. However, this goal is typically achieved only in situations of low density of crop canopies.\[14\]

CONCLUSION

The physical environment of the phyllosphere and the role of environmental stress in modulating microbial phyllosphere populations remains a field of investigation still relatively early in its development. While environmental parameters have been examined singly, the integration of multiple environmental effects has been experimentally difficult and, for the most part, not undertaken. Because of the direct effect of the environment on phyllosphere microbes, and the influence of some of these microbes on plant health, an expanded understanding of the phyllosphere physical environment is a goal for a more integrated understanding of plant disease management.

INTRODUCTION

Since the onset of the Industrial Revolution, the use of fossil fuel and the clearing of land have led to a dramatic rise in the concentration of carbon dioxide (CO2) in the atmosphere. This increase has significant implications for green plants because CO2 is the prime input to photosynthesis. Leaves are the first point of contact for the majority of carbon transfer from atmosphere to biosphere. This capture of carbon by leaves enables the growth of plants, which play a vital role in maintaining the environment and form the base of agriculture. Humans and other organisms depend on this thin layer of leaves for food. Leaves collect highly dilute CO2 from the atmosphere and concentrate and transform it into organic compounds. These compounds ultimately combine to form useful products (food and fiber). Leaf litter decomposition (by microbes) is a key process in agroecosystems through its role in carbon and nutrient cycling and storage. Leaves and their functions are pivotal in agroecosystems (and are sensitive to environmental change, especially rising CO2); this article provides a short overview.

PHYSIOLOGICAL PROCESSES IN LEAVES

Changes in atmospheric CO2 level have been shown to impact two major functions of leaves—photosynthesis and transpiration.[1–3] Crops grown under CO2 enrichment usually exhibit increased mass, which is attributed to more photosynthetic capacity and enhanced water use efficiency (ratio of CO2 assimilated to water transpired). There are, however, differences among plants. For example, plants with a C3 photosynthetic pathway often exhibit a greater response to high CO2. The CO2-concentrating mechanism in C4 species limits the response, but C4 plants can nevertheless exhibit growth stimulation because elevated CO2 can increase water use efficiency. The C3 plant generally benefits from both increased photosynthesis and water use efficiency. Increases in water use efficiency are notable, although the combined effects of CO2 on decreasing stomatal conductance and increasing leaf area and leaf temperature have resulted in modest reductions in estimated whole plant water use.[3]

An often reported consequence of enhanced photosynthesis is the accumulation of nonstructural carbohydrates.[1,2] Photosynthetic acclimation (a decline in photosynthesis over time) can be related to the buildup of nonstructural carbohydrates in leaves. The coupling of carbohydrate accumulation in leaves and acclimation is probably related to source-sink imbalances, with sink strength an important controlling factor. Some evidence shows a correlation between rooting volume and photosynthetic capacity as well as limitations in resource availability (e.g., soil nitrogen) influencing source-sink activity.[1,2] Increases in soluble carbohydrate concentration may repress photosynthetic gene expression, leading to reductions in photosynthetic pigments (e.g., chlorophyll and carotenoids) and important soluble proteins, including rubisco and antioxidant enzymes.[4] The photosynthetic apparatus may be more susceptible to photodamage due to decreased carotenoid content. There are some indications that increases in carbohydrates and decreases in protein are associated with a slight suppression of growth respiration and construction costs of leaves.[5] Rubisco represents a sizable portion of leaf nitrogen and plays a significant role in the reduction of foliar nitrogen concentration commonly found under high CO2 conditions.[1,2] Reductions in antioxidant enzyme activities observed under high CO2 may be reflective of less oxidative stress resulting from growth in CO2-enriched atmospheres.[4] Furthermore, antioxidant systems can differ according to plant genotype, suggesting differential resistance to biotic and abiotic stresses.

LEAF STRUCTURE AND DEVELOPMENT

Changes in the internal structure of leaves can occur under elevated CO2 conditions.[6] Consideration of leaf
structural changes may help interpret divergent findings with regard to photosynthetic acclimation. Fixation of CO₂ occurs at specific sites within the chloroplast and, under high CO₂, starch accumulation may change chloroplast structure and function (e.g., altered chloroplast integrity may limit carbohydrate transport to other organs). Both photosynthetic and assimilate transport capacity may also be altered by CO₂-induced shifts in mesophyll and vascular tissue. Leaves grown under elevated CO₂ have exhibited an extra layer (a third layer) of palisade cells as well as increased total mesophyll cross-sectional area and vascular tissue area. Stomatal density has been shown to decrease with elevated CO₂ in some, but not all cases. A further alteration is changes in epicuticular wax on high CO₂-grown leaves. Little is known about how CO₂ will affect trichomes. Changes in the leaf surface could affect water relations, susceptibility to pests and diseases, and surface properties that are important in chemical protectant application.

Plants grown under high CO₂ often exhibit increased area per leaf, greater leaf thickness, more leaves per plant, and higher total leaf area per plant, but effects on leaf area index are variable. Exposure to elevated CO₂ is thought to have little impact on rates of leaf initiation. Reported increases in leaf thickness and decreases in specific leaf area (leaf area/total leaf dry weight) are often the result of altered anatomy or increased starch accumulation. Although highly variable, increases in cell expansion may contribute to larger leaf size more than increased cell division. Increased expansion appears to result from greater cell wall relaxation and/or greater cell turgor. There is little information on how high CO₂ will affect leaf shape or duration.

**ENVIRONMENTAL CONSIDERATIONS**

CO₂-induced increases in leaf production and changes in leaf composition can significantly affect other trophic level organisms that utilize leaf tissue as a food substrate. The nitrogen concentration of green leaf material is often lower under high CO₂, whereas leaf carbon:nitrogen ratio, nonstructural carbohydrates, and secondary defense compounds can be increased. Effects on senescent leaf quality are more variable, but tend to be lower in magnitude. Changes in green leaves are relevant to phyllosphere organisms (fungi and bacteria living on leaf surfaces) and grazers (insects and livestock). The reproductive success of insects may be altered by diets of high CO₂-leaf tissue. However, the sparseness of information prevents generalization concerning the life cycle strategies of these organisms in a high CO₂ world. Information on this topic is critical for effective pest management (rates, timing, and number of pesticide applications may change under higher CO₂ environments). Trace gas emission (e.g., methane) associated with cattle production is related to low forage quality, thus any CO₂-induced downward shift in leaf nitrogen concentration may be significant.

Senesced leaves are a food source for soil organisms and a major component of carbon inputs for agroecosystems. Leaf litter input can be increased by high CO₂, but decomposition rates will vary by crop species. Some decomposition work suggests that CO₂-enriched cropping systems may store more carbon, decomposition may be limited by nitrogen, and nitrogen release from litter may be slowed. A more thorough understanding of carbon and nitrogen cycling is needed to predict the potential for soil carbon storage in agroecosystems. Green leaf material can also contribute to litter production in systems using cover crops. Plant growth stage and leaf tissue nitrogen need to be considered for cover crop termination to optimize resource availability (nitrogen and/or water) to the following crop. There are some indications that CO₂ can alter crop phenology, which may alter kill time for cover crops and subsequent timing of farm operations, including planting. Another complication is that herbicide efficacy can vary by weed species under elevated CO₂. This has important implications for future weed management (frequency of spraying/rate adjustments), including control of invasive species, and also raises questions about herbicide efficacy on cover crops.

**CONCLUSION**

Leaf responses to elevated atmospheric CO₂ will need to be further elucidated if we are to accurately understand and predict the development and growth of crops under future environmental conditions. Future research will need to address:

1. How alterations in leaf structure are related to both cellular and higher-level growth processes;
2. Whether increased cell division is driven by greater rates of cell expansion or by molecular cues;
3. The role of ultrastructural, anatomical, and morphological leaf adjustments in photosynthetic acclimation;
4. How CO₂-induced changes in leaf structure and leaf function will alter the degree of impact of multiple crop stresses (abiotic and biotic);
5. How CO₂-induced shifts in leaf quality and/or changes in leaf surface features (e.g., epicuticular waxes, trichomes) will alter herbivore and pathogen attacks;
6. Mechanisms for herbicide tolerance of plants grown under high CO₂;
7. How CO₂ alters leaf nutrient composition of cover crops over time (growth stage and phenology); and
With regard to leaf residue (green and senesced) supplying carbon and nitrogen to the soil, how elevated CO₂ will affect available crop nitrogen and the residence time of leaf-derived carbon in the soil.

INTRODUCTION

Legumes are one of the three largest families of flowering plants, with approximately 690 genera and about 18,000 species. Many legumes are currently used for nutraceutical and pharmaceutical purposes, whereas others contain medically important phytochemicals with potential for further use.

The legumes currently recognized by the Pharmacist’s letter/Prescriber’s letter natural medicines comprehensive database for nutraceutical effectiveness include guar [Cyamopsis tetragonoloba (L.) Taub.], soybean [Glycine max (L.) Merr.], winged bean [Psophocarpus tetragonolobus (L.) DC.], and fenugreek [Trigonella foenum-graecum L.]. Several other legumes are currently recognized for pharmaceutical effectiveness.

NUTRACEUTICALS

Many other legumes are or contain phytochemicals that are possibly effective or have been shown to have potential therapeutic effects. One of these is field beans (Phaseolus spp.), which provide one of the most important sources of dietary protein for human consumption. These legumes are rich in the amino acids lysine and tryptophane. Dry adzuki beans [P. angularis (Willd.) W. Wight] contain about 22% protein. Mung bean (P. aureus Roxb.) seed contains about 23.6% protein and 3.3% fiber. Rice bean (P. calcaratus Roxb.) pulse contains about 21.7% protein and 5.2% fiber. Lima (also known as butter bean) (P. lunatus L.) pulse contains 20.7% protein and 4.3% fiber. The most popular and widely used bean is the common bean known as French bean, kidney bean, runner bean, snap bean, and string bean. These bean pods have been shown to be possibly effective when used orally as a supportive treatment for the inability to urinate.[1,2] In addition, P. vulgaris L., winged bean, jicama [Pachyrhizus erosus (L.) Urban], Lablab purpureus (L.) Sweet, soybean, and kudzu [Pueraria montana var. lobata (Willd.) Maesen & S. Almeida] guar [Cyamopsis tetragonoloba (L.) Taub] are excellent sources of fiber (Fig. 1).[3] Winged bean leaves, flowers, shoots, immature pods, immature dry seeds, and tubers are edible and highly nutritious. The mature dry seeds are especially nutritious because of their high protein content (30–42%). However, the seeds can be soaked for 10 hours and then boiled for 30 minutes to rid them of any antinutritional components. Winged bean contains oil consisting of tocopherols that are antioxidants. These antioxidants improve the utilization of vitamin A in the human body.

Peanut (Arachis hypogaea L.) seed is rich in oil, containing about 53% oleic acid and 25% linoleic acid with about 30% protein. Peanut contains two important antioxidants: protocatechuic acid and lecithin.[3] Peanut oil is potentially useful for lowering cholesterol and preventing heart disease; however, allergic reactions are fairly common among the human population.[1] Aesculetin found in the peanut plant has been shown to be anti-inflammatory and a cancer preventive.[3] Lecithin exists in the peanut seed and has been found to range from 5000 to 7000 ppm. Lecithin has been shown to have antioxidant activity and some activity related to antialzheimeran.[3] It also appears to be possibly effective for treating gall bladder disease and hypercholesterolemia.[1]

Kudzu is used in traditional Chinese medicine for managing alcoholism, fever, cold, flu, and neck stiffness.[3] Kudzu contains other important phytochemicals—namely, isoflavones including daidzin, daidzein, and puerarin. Both daidzein and daidzin decrease alcohol consumption in rats.[4] A few products containing kudzu extracts are on the market; however, studies are needed to investigate the effects of kudzu in humans. The product known as Estroven, marketed by Amerifit, contains kudzu root isoflavones; a nutraceutical known as kudzu root is marketed by General Nutrition Center (GNC).

Velvetbean [Mucuna pruriens (L.) DC.] seed extract contains l-dopa, which is used as an antiparkinsonian.[3] Sabinsa Corporation markets velvetbean seed extract in powder form for use as a nutraceutical (Fig. 2).

Astragalus [Astragalus membranaceus (Fisch.) ex Link] has shown some preliminary evidence that it can reduce the chance of developing the common cold. The
active components appear to be in the root, consisting of saponins, flavonoids, polysaccharides, and coumarins. It is an antioxidant and improves the immune response by potentiating the effects of interferon. Several Vigna spp. including V. aconitifolia (Jacq.) Marechal, V. angularis (Willd.) Ohwi & H. Ohashi, V. mungo (L.) Hepper, V. radiata (L.) R. Wilczek, and V. subterranean (L.) Verdc. contain fiber from seed ranging from 9000 to 79,591 ppm. Plant fiber ranges from 31,700 to 286,000 ppm, whereas fruit fiber ranges from 9000 to 299,000 ppm in V. aconitifolia, V. mungo, and V. subterranean. Sprout seedling fiber ranges from 7200 to 94,500 ppm in V. radiata. See Table 1 for therapeutically effective nutraceuticals.

**PHARMACEUTICALS**

See Table 2 for currently recognized legumes with pharmaceutical effectiveness. The following discussion will include additional effective qualities for the phytopharmaceuticals listed in Table 2.

Beta-sitosterol found in jackbean [Canavalia ensiformis (L.) DC.] is a plant sterol similar to cholesterol; however, atherogenesis does not occur with beta-sitosterol because less than 5% is actually absorbed. Beta-sitosterol significantly improves urinary symptoms, increases maximum urinary flow, and decreases postvoid residual urine volume. It also significantly reduces total and low-density lipoprotein (LDL) cholesterol levels, but has little or no effect on high-density lipoprotein (HDL) cholesterol levels. Pectin is possibly effective for lowering cholesterol. Currently most of the therapeutic qualities from pectin have been discovered in citrus and apples. However, a substantial portion has been identified in the sunn hemp [Crotalaria juncea (L.)] stem. Guar gum (Fig. 3) is possibly effective for reducing triglycerides. Abbott Laboratories markets Ensure Glucerna, in which the key ingredient is guar gum for helping people with diabetes (Fig. 4). Several legumes have or contain potentially useful phytochemicals with pharmaceutical properties. Luteolin found in [Chamaecrista mimosoides (L.) E. Greene] and kaempferol from [Sesbania sesban (L.) Merr.] have anti-inflammatory, antioxidant, and cancer-preventive potential. Pinitol from [Macrotyloma uniflorum (Lam.) Verdc.] has antidiabetic and expectorant possibilities. Lecithin found in velvet bean (Fig. 5) and other legumes is likely effective when used for reducing hepatic steatosis in long-term parenteral nutrition patients and when used topically for dermatitis and dry skin. Some noteworthy discoveries for cancer treatments include plant-derived isoflavones. Genistein has thus far been shown to be more abundant in subclover (Trifolium subterraneum L.) than soybean or red clover (Trifolium pratense L.). Clinical trials have revealed that genistein inhibits the growth of both MCF-7 breast cancer cells and human mammary epithelial cells in vitro, whereas biochanin, another isoflavone found in subclover, is just as effective against these tumor cells but is five times less potent in the inhibition of normal cells. Furthermore, genistein has been shown to inhibit bladder cancer. Mimosine found in Leucaena species (Leucaena spp.) blocks cell cycle progression in MDA-MB-453 human breast cancer cells.

*aFound in jackbean; however, companies develop beta-sitosterol and rutin from other plant species.

(From Ref. [1].)
CONCLUSION

Both nutraceutical and pharmaceutical products have been made from legumes. Many legumes are currently known to be therapeutically effective, whereas others are undergoing research to ascertain whether they are effective in benefiting health-related problems. The use of such natural products has stimulated the interest of the general public because of the health-promoting properties of legumes. These possibilities make legumes very important for the future—and not just a hill of beans.

INTRODUCTION

Lesquerella produces a triglyceride oil that is two-thirds or more lesquerolic acid, a hydroxy fatty acid (HFA). Hydroxy fatty acids are now used in nylon-11 and nylon-6,10, lithium greases, coatings, sulfated and sulfonated oil, sebacic acid, ethoxylated oil, food grade lubricants, polyurethanes, and cosmetics. The current source of HFAs is ricinoleic acid from castor (Ricinus communis L.), which was formerly cultivated in the United States. Approximately 41,000 million tons are now imported, primarily from Brazil and India, at a value exceeding $100 million per year. Lesquerella is native to the United States and could be established as a domestic HFA source and reduce reliance on castor oil importation.

Lesquerella has several novel properties that set it apart from castor and other oilseeds. One property, is its oil functionality, including difunctional hydroxy moities (in contrast to other seed oils such as castor that are tri-functional). Lesquerella has been reported to contain natural estolides (secondary esters derived from the addition of a fatty acid moiety to the hydroxyl functionality of the hydroxy triglyceride) that improve performance of the oil. Estolides have been encountered in only a few other seed oils, and are not naturally found in castor oil (although they can be synthetically fabricated). Estolides have been shown to improve vegetable oil performance in motor oils by improving pour points (temperature at which the oil no longer pours), and estolides have also been used as viscosity modifiers in lubricating oils. The second of lesquerella’s novel properties is its antioxidants, converted from the seed meal fraction that contain unique glucosinolates and have superior oxidative stability properties. The seed meal also has a binder application, unique for seed meals. The third novel property is the seed coat of lesquerella, which contains a unique gum that has rheological properties equivalent to guar or xanthan that can be useful in coatings and food thickeners.

MARKET POTENTIAL

Large markets exist for hydroxylated oils as feedstock for lithium greases, polymers in paints and coatings, base stocks in lubricants, and in applications in the personal care industry.[1] Lesquerella could be established as a reliable domestic supply of oilseed for all these markets and simultaneously provide an alternative crop for farmers that would indirectly increase local profits. The unique chemical structure of lesquerella oil offers distinct advantages for the development of new applications.[2]

Increasing attention to environmental issues drives the lubricant industry to increase the ecological friendliness of its products.[3] The industry has, for the last decade, been trying to formulate biodegradable lubricants with technical characteristics superior to those based on mineral oil (petroleum). Volumes of lubricants, especially engine oils and hydraulic fluid, are relatively large and most are petroleum based. Hydraulic fluids are consumed at 5 million metric tons (MT)/year in the United States, and have the highest need for biodegradable lubricants.[3]

Until now, petroleum-based lubricants have been superior to biodegradable vegetable oils because of their lower pour points and higher oxidative stability.[3] Some vegetable oils (such as soybean) require up to 30% synthetic additives to improve their performance. However, the triglyceride estolides that are found in species of the genus Lesquerella overcome this vegetable oil deficiency by blocking unsaturation and providing branches that lead to lower pour points.[4] In fact, vegetable-based lubricants with synthetic additives still do not approach the properties of estolides. The commercialization of lesquerella
Lesquerella Potential for Commercialization

Lesquerella requires 25 to 26 inches of irrigation water for maximum seed yield, as compared to 30 to 40 inches for cotton. Nitrogen/acre amounts of 50 to 100 lb. increased lesquerella biomass and seed yields. Lesquerella can be efficiently harvested by direct combining. Maximum seed yields have been obtained with a planting density of about 400,000 plants/acre (approximately 5.0 to 6.0 lb. of seed/acre). Crop rotations have been studied and there have been no reports of allelopathy.

Because lesquerella will be grown in irrigated arid and semiarid regions of the southwest United States, a salt-tolerant line has been developed that is able to grow in these areas where drainage effluents are reused and where the crop could benefit marginal agricultural lands. In addition, lesquerella has been shown to be a potential phytoremediator of selenium (Se)-contaminated soils, because the plant can accumulate this harmful trace element in its leaves and stems. High levels of Se found in areas such as the San Joaquin Valley of California pose health threats to humans, livestock, and wildlife. Following harvest, the seed oil would be utilized for the proposed industrial purposes described earlier, and the bioaccumulated plant parts that remain could be removed from the area.

In the production areas where lesquerella is likely to be grown, control of weeds is extremely important. In fact, weed control could be a major factor limiting establishment of commercially-viable lesquerella production in the United States Lesquerella is slow to establish, making the crop less competitive with grass and broadleaf weeds that emerge in crop rows and cannot be removed mechanically. For lesquerella to be produced economically at industrial scale on commercial growers’ fields, herbicides must be registered. Several economical and environmentally safe herbicides for this crop have been identified in extensive field research studies.

CONCLUSION

Agricultural research and extension personnel, USDA/ARS scientists, and agribusiness representatives have identified 21 counties in Arizona, New Mexico, and Texas believed to hold the greatest potential for lesquerella commercialization. Irrigated acreage in these counties totals almost 1.4 million. Lesquerella will not necessarily replace current commodity crops but will be placed in rotation (e.g., a 2-year, 3-crop rotation of lesquerella, grain sorghum, and cotton). Over the long term, as lesquerella markets strengthen, acreage increases, and net returns remain competitive with other crops, lesquerella could replace commodity crops with negative net returns. Wheat, for example, produced on 320,000 acres in 17 of the 21 aforementioned counties, reported the most crop
budgets with estimated negative net returns. Abandoned cropland in the Trans Pecos region of west Texas alone accounts for another potential growing base of 180,000 acres in addition to irrigated acres. Soil erosion on lesquerella plantings will not be an issue because the crop provides soil cover during the fall and winter, and stubble can be left on the land after harvest.

Because new industrial products unique to lesquerella will be developed, lesquerella would not be expected to replace castor in the event it is reintroduced as a U.S. crop. Therefore, domestic supplies of HFAs would not depend on a single crop. The two crops could be produced in different seasons—lesquerella would be planted in the fall and harvested in late spring, whereas castor would be planted in the spring and harvested in late fall. There would be rotational opportunities for both crops. Castor has a high water requirement, and would not be produced in arid and semiarid environments where lesquerella is best suited. Multiple production regions would provide a more reliable domestic supply of HFA. This in turn could encourage further research and new product development, thus opening additional markets for both crops.

INTRODUCTION

Light-harvesting complexes (LHCs) are distinct integral-membrane, pigment-protein assemblies that serve, in association with reaction centers, as antennae. LHCs collect and regulate delivery of the light energy that drives photosynthesis. In green plants (Chlorophyta), LHCs are encoded by a nuclear multigene family and post-translationally imported into the chloroplast, where they noncovalently bind chlorophyll (Chl) $a$, Chl $b$, and carotenoids.

LHC GENE FAMILY

A large nuclear gene family, known as $Lhc$ genes, encodes LHC proteins (LHCPs) that range from 20 to 30 kDa in mass. Duplication and divergence of the $Lhc$ gene family have produced a large number of functionally distinct antenna proteins, of which there are two main groups. The first consists of $Lhca$ genes ($Lhca$–$Lhcd$), encoding LHCPs associated with photosystem (PS) I (LHCI). The second group includes the $Lhcb$ genes ($Lhcb1$–$Lhcb6$), encoding LHCPs primarily associated with PSII. Each of these individual designations can include several related derivatives, and some plants are known to have up to 20 different $Lhc$ genes. The major LHC associated with PSII (LHCII) is the most abundant Chl-binding protein. LHCII exists as a trimer and the apoproteins, encoded by $Lhcb1$ and $Lhcb2$, bind over half the Chl in the thylakoid membrane. Four to six trimeric LHCII are associated with each reaction center. $Lhcb3$–$6$, apoproteins of the minor antenna, exist in roughly a 1:1 ratio with PSII and serve to connect the main antennae, LHCII, with the reaction center.

In vascular plants, transcription of $Lhc$ genes is tissue specific and regulated by a network of signals initiated by environmental cues. Signaling molecules such as phytochrome, cryptochrome, the Chl biosynthetic precursor Mg-protoporphyrin IX and Mg-protoporphyrin monomethyl ester, a Chl biosynthetic protein Mg-chelatase subunit H, and plastid redox sensory molecules such as plastoquinol have been implicated in regulation of transcription of $Lhc$ genes. These molecules are involved in different signal pathways that either upregulate or downregulate the expression of these nuclear encoded genes.$^{[1]}$

The amino acid similarity between homologous LHC proteins from different plant species is greater than 90%. Differences among the various types of LHCPs, i.e., Lhca1 vs. Lhcb1, are much more substantial. However, two regions, the first membrane-spanning and the third membrane-spanning regions of the proteins, are highly conserved. Within these conserved regions resides a unique motif, EXXH/NXR, repeated in both the first and third membrane-spanning regions, which unequivocally identifies the protein as a non-bacterial LHCP (Fig. 1). Conservation of the first and third helices has led to the hypothesis that LHCPs evolved by duplication of a two-helix membrane-spanning polypeptide to form a four-helix membrane-spanning protein, with loss of the fourth helix.$^{[2]}$

STRUCTURE/FUNCTION

The structure of the $Lhcb1$ gene product from higher plant, as determined from the structure resolved to 3.4 Å by electron diffraction,$^{[3]}$ revealed the organization of pigments that are bound to three $\alpha$-helical membrane-spanning regions and a small, C-terminal amphiphilic helix. Bracing helices 1 and 3 are two molecules of lutein. Twelve Chl molecules were detected, eight of which are ligated through coordination with amino acid sidechains, while ligands to the remaining four Chls were not identified. Biochemical analysis has shown that $Lhcb1$ and $Lhcb2$ protein complexes coordinate seven Chl $a$, five Chl $b$, two lutein, one neoxanthin, and substoichiometric amounts violaxanthin. Although LHCPs share sequence homology, differences in their pigment-binding preferences have been revealed. Analyses of the minor complexes show $Lhcb$ 4–6 gene products ligate fewer Chls than $Lhcb1$ and $Lhcb2$. $Lhcb4$ binds eight Chls (six Chl $a$ and two Chl $b$), $Lhcb5$ binds nine Chls (six Chl $a$ and three Chl $b$), while $Lhcb6$ binds 10 Chls (five Chl $a$ and five Chl $b$). The minor LHCs also ligate fewer xanthophylls (one lutein, 0.5 neoxanthin, and 0.5–1 violaxanthin).$^{[4,5]}$

It is likely, on the basis of the sequence homology, that $Lhca$ gene products share a high degree of
structural similarity with the LHCII proteins. Similarly to the minor antennae of PSII, apoproteins of LHCI coordinate six to nine Chl $a$, three Chl $b$, one lutein, 0.5 violaxanthin and, instead of neoxanthin, bind substoichiometric amounts of $\beta$-carotene. LHCI can be fractionated into two populations based on their fluorescence emission maximum at 77 K. LHCI-680 is composed of Lhca2 and Lhca3, whereas the second type, LHCI-730, is a heterodimer of Lhca1 and Lhca4.

A correlation seems to exist between the location of an LHC and its preference for binding Chl $a$ over that of Chl $b$. Lhcb4 and Lhcb5 monomers are located adjacent to the PSII core and preferentially bind Chl $a$, as does Lhca1–4 dimers, which are located directly adjacent to PSI. The most peripheral LHCII trimers contain almost equal numbers of Chl $a$ and Chl $b$. This overall structure is closely related with function. LHCs broaden absorption bands by using pigments different from those located in and near the reaction center, which increases the probability that photons not absorbed by the reaction center will be captured. Once the energy is captured, transfer of exciton energy within the LHC is ultrafast, occurring in the range of hundreds of femtoseconds. The primary purpose of LHCs is to transfer captured excitation energy to Chl $a$ in a photochemical reaction center for charge separation. Exciton energy is transferred from LHCs to reaction centers on a picosecond timescale and is essentially 100% efficient.

LHCI is also involved in redistribution of excitation energy between PSII and PSI by state transitions that occur upon overexcitation of PSII. When PSII is saturated with light energy with respect to PSI, the plastoquinone pool becomes reduced and activates a kinase bound to the cytochrome $b_{6,f}$ complex. This process results in phosphorylation of the stromal facing N-terminal portion of the major trimeric LHCII, leading to a disassociation from PSII reaction centers and monomerization of LHCII. Lhcb1 and Lhcb2 monomers move laterally out of the grana into the stromal lamellae where they redirect their energy to PSI. A second, more static strategy that plants have developed to redistribute energy is to quench excitation energy and dissipate that energy through nonradiative mechanisms. The xanthophyll, zeaxanthin, has the most favorable energy level to efficiently quench excited Chl and has been shown to be effective in dissipation of potentially damaging excess energy as heat. The relatively high content of violaxanthin, which is available for conversion to zeaxanthin, is associated with the minor LHCs. Therefore, Lhcb4, 5, and 6 may participate in nonphotochemical quenching as a
means to redirect excitation energy away from the reaction center of PSII.

**IMPORT/ASSEMBLY**

Nuclear encoded LHCPs are synthesized in the cytoplasm as higher molecular weight precursors and imported into the chloroplast, where the N-terminal transit sequence is removed by a protease in the stroma. Not surprisingly, events occurring at the chloroplast envelope are crucial for in vivo import of LHCP.

For import into the chloroplast, there are several regulatory points that nuclear-encoded proteins must pass. First, LHCP precursors engage a general chloroplast import apparatus. The apparatus is composed of two distinct multi-subunit translocation machines, called Toc and Tic, located in the outer and inner membranes, respectively. Toc is sensitive to nucleotide concentrations and modulates receptor-LHCP precursor binding through GTP/GDP binding cycles. At the inner envelope, redox sensitive components of the Tic complex can regulate import based on the redox state of the chloroplast.[9]

Once the import apparatus is engaged, a second, and more functional/structural requirement at the inner envelope must be met. Chl must be available to interact with LHCP. If sufficient Chl is not available or mutations are present in the Chl binding sites of the apoprotein, LHCP import is aborted.[10] Only under certain conditions (growth on an organic carbon source), and with the more hydrophobic LHCs, is interaction with Chl a sufficient to retain LHCs in the chloroplast. Otherwise, Chl b is required. The stronger coordination bond between Chl b and amino acid sidechain ligands in LHCs enhances their import into the chloroplast and assembly of LHCs.[11]

Assembly of LHCs is wholly dependent upon interaction with Chl a, Chl b, and carotenoids. Complexes deficient in Chls or xanthophylls are unstable and subject to proteolysis. During early development, i.e., the conversion of proplastid to chloroplast, LHCs assemble on low-density (inner envelope) membranes and within seconds become connected to reaction centers. Other nuclear encoded proteins such as cpSRP54 and cpSRP43 may also facilitate assembly at the membrane.[10]

In summary, membrane-bound LHCs are transcriptionally controlled, multigene family proteins that require Chl a, Chl b, and xanthophylls for assembly and to function in the regulation of exciton energy flow into and away from the photosystems in green plants.

Lipid Metabolism

Jean-Claude Kader
Université Pierre et Marie Curie, Paris, France

INTRODUCTION

Lipids can be defined as a group of fatty-acid-derived compounds soluble in nonaqueous solvents. They constitute a broad family of molecules, which is particularly large in higher plants since more than 300 different fatty acids (FAs) have been characterized. Lipids are important constituents of plant cell membranes and are involved in physiological processes linked to the responses of plants to environmental conditions, to defense reactions, and to intracellular signaling pathways. Lipids are also an important form of carbon storage in seeds. Oilseeds are among the most ancient crops, cultivated for thousands of years as sources of products used for food and for industrial products such as cosmetics or lubricants. Both uses have led to an increase in the demand for oilseeds, and world oilseed production (mainly soybean, rapeseed, sunflower, palm, cottonseed, and peanut) has expanded in the last 50 years from 160 to 300 million tons per year.

In order to improve the quality of plant oils (seeds and fruits), it is important to increase our knowledge of the metabolism of plant lipids. It is the aim of this article to summarize the lipid biosynthetic pathways and to present the exciting perspectives offered by the metabolic engineering of oils.

STORAGE AND MEMBRANE LIPIDS HAVE DIFFERENT FATTY ACID COMPOSITION

The major lipids of plant cell membranes are phospholipids (mainly phosphatidylcholine, phosphatidylethanolamine, and phosphatidylinositol) and, in the plastid membranes, galactolipids (mainly monogalactosyldiacylglycerol). It is remarkable that the main FAs present in these membrane lipids are also found in triacylglycerols (TAGs), which are the storage lipids. These FAs are predominantly palmitate (16:0) (the first number refers to the number of carbon atoms, the second to the number of double bonds), stearate (18:0), oleate (18:1), linoleate (18:2), and linolenate (18:3). Seeds contain, in addition to these common acyl chains, a very large diversity of FAs referred to as “unusual.” These FAs vary by their chain length, from 8 to 14 carbons in Lauraceae or from 20 to 24 carbons in Brassicaceae. Other oils accumulate FAs with double bonds at positions not usually found in membrane lipids such as petroselanic acid (16:1) or acyl chains containing hydroxy, epoxy, or acetylenic functional groups. The reason for such a large diversity is still unknown, but the fact that these FAs are excluded from membranes and accumulate in TAGs help plants to tolerate high levels of these unusual lipids. These FAs have important industrial applications (lubricants, paints, detergents, cosmetics) due to their unique chemical properties. However, the production of such compounds at a high level is not possible since their sources are plants that are not adapted to classical agricultural practices. This led to the idea to introduce genetic engineering approaches to adapt common crops to industrial needs.

AN INTRACELLULAR COOPERATION IS NEEDED FOR LIPID BIOSYNTHESIS

It is remarkable that the biogenesis of plant glycerolipids needs a complex intracellular cooperation between the plastid and the endoplasmic reticulum. Two distinct pathways are operative: the “prokaryotic” one, localized within the plastid, and the “eukaryotic” pathway, which requires cooperation between the two cell compartments. The elucidation of these metabolic pathways is the result of early biochemical studies and of approaches of molecular biology and molecular genetics, which, in the case of the model plant Arabidopsis thaliana, have allowed the characterization of mutants deficient in enzymes of lipid metabolism. In less than 10 years, these investigations resulted in the cloning and characterization of the key enzymes of the lipid pathways. A survey of genes for plant lipid metabolism has recently been published by searching the public databases for sequences coding for 65 polypeptides involved in lipid biosynthesis and degradation.

PLASTIDS PLAY A CENTRAL ROLE IN FATTY ACID SYNTHESIS

In the stroma of plastids, the first steps of fatty acid biosynthesis are carried out (Fig. 1). The stepwise condensation of C2 units to a growing acyl-chain attached...
to acyl-carrier protein (ACP) leads to the formation of saturated acyl chains with palmitoyl-ACP (16:0-ACP) as a major product. However, shorter acyl chains could be formed depending on the plant species. The group of enzymes involved in fatty acid synthesis is called fatty acid synthase (FAS), which is, in animals and yeast, a multifunctional enzyme complex characterized by large subunits. By contrast, FAS from plants includes at least 12 separate proteins functioning rather like a metabolic pathway. A further step is the elongation of 16:0-ACP to 18:0-ACP by a \( \beta \)-ketoacyl synthase (the mutant \( \textit{fab1} \) of \textit{Arabidopsis} is deficient in this enzyme) followed by a desaturation by a stearoyl-ACP-desaturase (corresponding mutant \( \textit{fab2} \)), which introduces a double bond at carbon 9 and forms oleoyl-ACP. This desaturase, soluble in the stroma, is unique among all other acyl-desaturases, which are integral membrane proteins. A key step is then termination, which is catalyzed by thioesterases that hydrolyze the acyl-ACPs to produce free FAs. These FAs are exported from the plastid to the endoplasmic reticulum and participate in the eukaryotic pathway. Some of the acyl-ACPs are used within the plastid and enter into the prokaryotic pathway involving a glycerol-3-phosphate acyltransferase (8) and lysophosphatidate acyltransferase (9), thus allowing the formation of phosphatidylglycerol (PG) (10) or monogalactosyl-diacylglycerol (MGDG), which is of prokaryotic type (16 carbons at \( \text{sn}-2 \) position) (11). The eukaryotic pathway involves an export of the various acyl-CoAs to the endoplasmic reticulum by an unknown mechanism (12). Acyl-CoAs are inserted into membrane phospholipids, mainly phosphatidyl-choline (PC), through glycerol-3-phosphate acyltransferase (13), lysophosphatidate acyl-transferase (14), phosphatidate phosphatase (15), and CDP-choline : 1,2 diacylglycerol-choline phosphotransferase (16). The FAs of PC are desaturated (17,18). Some of the FAs are used for the synthesis of other phospholipids (19). PC molecules exchange their FAs with those of the acyl-CoA pool by the action of acyl-CoA lyso-PC-acyltransferase (20). The acyl-CoA pool also comprises other FAs modified by various enzymes, depending on the plant species. The FAs allow the synthesis of triacylglycerols (TAGs) through a series of reactions (13–16) including one step unique to TAG formation, the diacylglycerol acyltransferase (22). The final step of the eukaryotic pathway is the reentry of the FAs into the plastid (23) where they form eukaryotic lipids, mainly MGDG esterified by 18 carbons in both positions (24).
prokaryotic pathway, allowing the synthesis of plastidial membrane lipids such as phosphatidylglycerol, galactolipids, or sulfolipids.\textsuperscript{1,5} The importance of the prokaryotic pathway depends on the plant species and is minor in oilseeds.

**THE ENDOPLASMIC RETICULUM IN DIVERSITY OF PLANT LIPIDS**

The exported FAs are involved in the eukaryotic pathway and are esterified to CoA. The acyl-CoAs join the acyl-CoA pool, which is used partly for the production of membrane lipids such as phosphatidylcholine and other phospholipids. In addition, the diacylglycerol moiety of phosphatidylcholine partly returns to the plastid by an unknown mechanism and is used for the synthesis of modified eukaryotic plastidial lipids, mainly galactolipids that have 18:3 in both \textit{sn} positions. These galactolipids differ from the prokaryotic species, which have 16:3 at one of the two positions. The other part of the acyl-CoA pool is used to synthesize TAGs, a process highly active in oilseeds. Several enzymes are involved in these pathways, such as membrane-bound desaturases (oleate desaturase (also named FAD2) and linoleate desaturase (FAD3)) and various types of acyltransferases. One step unique to TAG synthesis is the final one catalyzed by a diacylglycerol transferase specific to the third carbon of the glycerol backbone. Depending on the plant species, other specific enzymes may operate, such as elongases, epoxidases, hydroxylases, and acetylenases. This enzyme diversity explains the broad spectrum of TAGs found in oilseeds. TAGs accumulate in subcellular organelles called oil bodies and are hydrolyzed to provide energy for germination and other processes.\textsuperscript{7} The intensity of the flux of acyl moieties between the two cell membranes and the channeling of FAs toward either membrane or storage lipids depend on the plant species or the tissue considered.

**WHAT ARE THE GENETIC ENGINEERING TARGETS?**

The improvement of seed oil quality requires either molecular markers to help breeding or cloned genes to manipulate their expression in planta.\textsuperscript{14,7} The two main directions are to modify the level of expression of a gene of interest or to introduce a foreign gene into a common crop to broaden the range of FAs offering industrial applications. Some of the successful experiments were to improve the quality of edible oils by increasing the proportion of monounsaturated FAs. This was achieved, for example, in soybean by underexpressing the oleate desaturase. Another successful strategy was to increase the amount of saturated FAs, used for margarines and shortenings, by antisense RNA suppression in rapeseed of a gene coding for stearoyl-ACP desaturase. The introduction of a foreign gene was successfully achieved for lauric acid (12:0), which is used for the production of detergents. High laurate oil, commercially sold from 1995, was obtained by expressing a thioesterase isolated from California Bay that terminates the elongation process at a length of 12 carbons. Other FAs interesting for lipochemistry are erucic acid (22:1), a product of an elongase complex in rapeseed; ricinoleic acid (18:1-OH), formed in castor bean by a hydroxylase, and \( \gamma \)-linolenic acid (\( \gamma \)-18:3), synthesized in borage by a specific type of desaturase. These FAs have been produced in model plants by expressing genes corresponding to these enzymes. The latter enzymes belong to the vast family of desaturases (FAD2 type) or are biochemically close to them. A site-directed or random mutagenesis strategy of desaturases offers perspectives for enzyme engineering.\textsuperscript{7}

**CONCLUSION**

It is easy to conclude that the knowledge of plant lipid metabolism, which has greatly progressed in the last decade, offers exciting perspectives for improving oil quality for food and industrial applications and for producing novel compounds that are renewable and environmentally friendly. Additional examples are the synthesis of polyhydroxybutyrate, a biodegradable plastic, by expressing in plants several bacterial genes or the development of oils suitable for use as lubricants or sources of fuels. Future research will be devoted to understanding the role of membrane lipids in the responses of plants to environmental factors or to pathogens. Other promising investigations will be to study the involvement of phosphoinositides in the signal transduction pathways and the participation of fatty acid derivatives (oxylipins, jasmonate) and enzymes (phospholipases, lipoxygenases) in these important processes.

REFERENCES

INTRODUCTION

There have been very few continuous, planned, long-term selection studies for biochemical traits in plants even though such studies provide valuable information about limits to selection, genetic control of biochemical traits, and potential for improvement of chemical composition of a crop. In this article, results of the longest, continuous selection program for chemical composition in higher plants will be reviewed and the implications of the results of that program to plant breeding progress will be discussed.

BACKGROUND

There have been very few long-term selection experiments for biochemical traits in plants. The earliest known experiment of this type (begun in 1786 and continued until 1830) was the transformation of the fodder beet into the sugar beet (*Beta vulgaris* L.) by selection for sucrose concentration in the beet root.[1] This selection was done well before the discovery of genetics. Thus data, which would allow measurement of genetic variability or determination of genetic control of sucrose concentration, are not available. However, it had the very practical result of providing the groundwork of an entirely new industry and changing a fodder crop into a food crop. In addition, the success of this selection likely provided the impetus for the Illinois long-term selection experiment for oil and protein in corn (*Zea mays* L.), the longest continuous selection experiment in higher plants. The Illinois experiment is the major emphasis of this article.

THE ILLINOIS LONG-TERM SELECTION EXPERIMENT

Background

Selection for oil and protein concentration in the corn kernel was started in 1896 at the University of Illinois by Hopkins.[2] In 2003, the experiment is in its 104th generation. Hopkins was a soil chemist who recognized the importance of improving the quality of corn for animal feeding. The success of selection for sucrose, which resulted in the sugar beet, likely influenced Hopkins’ decision to select for oil and protein in corn. Details of the selection procedures have been described.[3] Briefly, Hopkins measured oil and protein concentrations of 163 ears from the open-pollinated corn cultivar “Burr’s white.” He selected the 24 ears highest in protein to initiate the Illinois High-Protein (IHP) strain; the 24 ears highest in oil to initiate the Illinois High-Oil (IHO) strain; the 12 ears lowest in protein to initiate the Illinois Low-Protein (ILP) strain; and the 12 ears lowest in oil to begin the Illinois Low-Oil strain (ILO). Over the years, minor modifications were made to the selection procedure but a form of mass selection was used throughout.[4] In generation 48, reverse selection [i.e., selection for low oil in IHO, to produce Reverse High Oil (RHO), and for high oil in ILO, to produce Reverse Low Oil (RLO), with similar selection for protein in IHP and ILP to produce Reverse High Protein (RHP) and Reverse Low Protein (RLP)] was initiated to determine whether genetic variability had been exhausted.[5] In generation 7 of RHO, selection for high oil was used to initiate the Switchback High-Oil (SHO) strain.

Results

Progress from selection is still being made after over 100 years in IHO, SHO, RHO, and RLO (Ref. [4] and Fig. 1). The rate of gain in SHO has been slightly greater than in IHO, and the mean for SHO is now near that of IHO (Fig. 1). The means for RLO and RHO are now nearly the same, but both are lower than the original mean. ILO reached a lower limit of selection when oil became so low (<1.0% oil) that it was no longer measurable.

Progress from selection in IHP was not as uniform as in IHO (Fig. 2). Following generation 52 when N fertilizer was added to IHP, the rate of progress increased. ILP reached a lower limit after approximately 65 generations. Although the protein level (4.5% protein) was still measurable, no further progress was made. A selection limit may have been reached for RHP because the protein level has reached the level at which progress ceased in ILP (Ref. [6] and Fig. 2).

As measured by realized heritability, response to selection was symmetrical in IHO and ILO. However,
Fig. 1  Oil response.

Fig. 2  Protein response.
change per generation, after generation 9, was much greater in IHO than in ILO (Fig. 1) because of the much larger selection differential in IHO. The pattern was not as clear in IHP and ILP. For the first nine generations, realized heritabilities were similar in IHP and ILP, but in later segments of the experiment, realized heritabilities in IHP were higher than in ILP. Change per generation after generation 9 was much higher in IHP than in ILP (Fig. 2). Reverse selection was effective in all four strains. In general, change per generation was higher in RHP and RHO than in RLP and RLO.

**Correlated Response**

In this experiment, selection was for a single trait measured in terms of concentration. Because concentration of one component is relative to the constitution of the entire kernel, when oil or protein concentration changes, the absolute concentration of another component of the kernel must change. Increases in oil in IHO and SHO were accompanied by decreases in percentage of starch and kernel weight, increases in percentage of germ, and small increases in percentage of protein. Increases in protein in IHP and RLP were accompanied by decreases in percentage of starch, but there were no significant changes in percentage of oil. The fact that increases in percentage of oil or percentage of protein are accompanied by decreases in percentage of starch is not surprising given that starch makes up about 70% of the dry weight of the kernel.

**Genetic Control of Oil and Protein**

The number of effective factors differentiating IHO and ILO was estimated as 54, whereas the number differentiating IHP and ILP was 123. The average frequency of the favorable allele for high oil in the original population was estimated as 0.20. For protein, the estimate of the average frequency of the favorable allele was 0.24. Using these data, it is possible to show that all the progress which has been made in the IHO and IHP strains can be accounted for by a low initial gene frequency and a large number of genes segregating in the original Burr’s white population. Alternatively, Walsh suggests that gain based on mutational variance is expected to eventually exceed that from gain based on residual segregation from the original population.

In addition to providing valuable insights into the process of selection, this experiment has produced strains that provide a unique set of materials for use in molecular marker studies aimed at identifying and locating genes that control oil and protein concentration in the grain. One of the requirements of such studies is parents differing widely for the trait. IHP and ILP, or IHO and ILO are as different in protein or oil as any strains known. Thus crosses between them should be segregating for many genes. These strains are currently being used in studies aimed at identifying quantitative trait loci (QTL) affecting oil and protein concentrations. The number of QTL identified is much smaller than expected based on estimates of the number of effective factors. However, limitations of the QTL studies, such as resolving linked loci and difficulties resulting from small sample size, may account for this discrepancy.

These strains also provide unique germplasm for studying the physiology of oil and protein production in corn. Studies of the IHP and ILP strains have shown unique differences in the way in which the two strains utilize nitrogen to produce grain protein.

**IMPLICATIONS TO BREEDING**

The progress made in the IHP and IHO strains is such that the current means (20.5% oil in IHO and 30% protein in IHP) are approximately four and three times the means in the original population. Another way of measuring progress, which can be translated to other traits, is the number of additive standard deviations (σ) of progress made in a given strain. For IHO, gain was 21σ, and for IHP, gain was 28σ. These gains from selection are well beyond what might have been predicted from the distribution of oil and protein values in the original population. What would grain yields be if as much progress could be made for yield as was made for oil and protein? In two populations where good estimates of means and σ for grain yield were available, gains of 24σ were estimated as 33.3 and 27.4 t ha⁻¹ in the two populations. Predicted yield of the hybrid between the strains was 44 t ha⁻¹. Given that the average yield of corn in Illinois is approximately 9.1 t ha⁻¹, this means that yields could quadruple before reaching a limit. Thus the results from this experiment suggest that much more progress from selection may be made than is usually considered possible.

**CONCLUSION**

The limit to selection has not been reached for high protein or high oil. Thus continued gains are to be expected from additional generations of selection. By using newer techniques for identifying QTL in crosses of IHP × ILP and IHO × ILO, there is promise for identifying more QTL controlling oil or protein. Such studies should also identify QTL responsible for the negative correlation between protein and starch, or between oil and starch.
Continued use of the strains to study protein and oil metabolism should lead to enhanced understanding of genetic control of grain quality in corn.

Long-Term Selection: Repeatability of Response in Finite Populations

Bruce Walsh
The University of Arizona, Tucson, Arizona, U.S.A.

INTRODUCTION

With finite population size comes genetic drift, random change in allele frequencies because of random sampling of gametes to form the next generation. Even when loci are under selection, genetic drift is still potentially important in that favorable alleles can become lost from a population because of drift. A direct consequence of drift is considerable variation in the response to selection, even among initially identical replicate lines under identical selection. Under long-term selection, mutation introduces additional variation in response by introducing different mutations in different lines.

A SIMPE EXAMPLE

Consider a cross between two inbred lines—the first fixed for favorable alleles (A, B) at two loci and the second fixed for favorable alleles at two different loci (C, D)—so that the resulting cross is AABBccdd × aabbCCDD. All F1 individuals are AaBbCcDd, carrying favorable alleles at each of the four loci. Genetically identical F1 individuals form the replicate lines that are then subjected to identical selection.

If selection is weak on a favorable allele (as would occur if the allele has only a small effect on improving the trait of interest), the probability that the allele is fixed is near 1/2. Hence, when considering the A locus, 50% of the lines will eventually become AA; the other 50% will be aa. In the absence of selection, the probability that a line will eventually be fixed for favorable alleles at all loci by chance (AABBCCDD) is \( (1/2)^4 = 0.0625 \). The probabilities that a line is fixed for favorable alleles at only three, two, or one loci are likewise found to be 0.25, 0.375, and 0.25. Thus one expects considerable genetic variation between lines, hence differences in the mean performance of the replicate lines. This variation is expected to occur even though the initial lines were completely identical and subjected to identical selection. Obviously, slight variations between the genetic composition of the initial lines and/or variation in the nature of selection on the lines will generate additional variation in line performance.

A final point is that lines identical in performance may, in reality, be fixed for different alleles. For example, two lines each fixed for two favorable alleles may (in fact) actually be genetically very different (e.g., AABBcccc and aabbCCDD). Crossing these two fixed lines and selecting allow for the possibility of recovering a new line fixed for all four favorable alleles. Thus the amount of genetic variance between fixed replicate lines is of considerable importance in breeding. If the between-line genetic variance is high, crossing lines followed by a second round of selection can result in further improvement in the best performing lines. Similarly, if the variance is low, there is little to be gained by crossing and further selection.

VARIANCE IN LINE MEANS UNDER PURE DRIFT

The expected variation in the means of lines experiencing only drift provides a useful starting point for examining the expected variance in response under selection. In particular, if a trait is determined by a large number of loci each of small effect (so that selection is weak on each), the allelic frequency dynamics is often much closer to those expected under drift than to those for selection. Consider one locus with two alleles, Q and q, and suppose (relative to the mean trait value) that the genotypes QQ:Qq:qq contribute values of \( 2a: a(1 + h): 0 \) to the trait of interest. In a finite population, in the absence of mutation, eventually either allele Q or q is fixed. Under strict drift, the probability \( U \) that allele Q is fixed is just equal to its initial frequency \( p \). Likewise, \( 1 - U = 1 - p \) is the probability that allele q is fixed instead. Because ultimately the genotypes become either QQ or qq, the expected contribution from this locus becomes:

\[
E[R] = 2ap + 0^* (1 - p) = 2ap \tag{1a}
\]

For example, if QQ individuals are, on average, 4 cm taller than qq individuals, then \( 2a = 4 \), and if (say) the initial frequency of allele \( Q \) is \( p = 0.75 \), the average response from this locus is \( 2ap = 3 \) cm. Recalling that we can write the variance of a random variable as \( E(x^2) - \mu^2 \), where \( \mu \) is the mean value and \( E(x^2) \) is the
average value of the square of the variable, the variance about the expected contribution becomes:

\[
\text{Var}(R) = (2a)^2 p + 0^2(1 - p) - R^2
= 4a^2 p (1 - p)
\]  

(1b)

If the alleles show no dominance \((h=0)\) so that the value of \(Qq\) is exactly intermediate to \(QQ\) and \(qq\), the additive genetic variance \(V_A\) contributed by the locus equals \(2a^2 2p(1-p)\); hence the variance in response is just twice the additive variance. Because the phenotypic covariance between a parent and its offspring is \(V_A^2\), \([1,2]\) in theory, one could estimate the expected variance in response under strict drift from twice the parent–offspring covariance. When dominance or epistasis is present, this simple relationship between additive variance and variance in response no longer holds.

**VARIANCE IN RESPONSE UNDER DRIFT AND SELECTION**

When selection occurs, the above expressions for the expected mean and variance in response still hold, provided we replace \(p\) by \(U\), the probability of fixation under drift and selection. Substituting \(U\) for \(p\) in the above expressions gives:

\[
E[R] = 2aU + 0(1 - U) = 2aU
\]

(2a)

and

\[
\text{Var}(R) = (2a)^2 U + 0^2(1 - U) - R^2
= 4a^2 U (1 - U)
\]

(2b)

Figure 1 plots the variance in response as a function of \(U\). Note that the variance achieves its maximum value \((a^2)\) at \(U=1/2\). Note from the figure that a mild amount of selection may actually increase the variance in response relative to that under strict drift. If \(Q\) is favored by selection, its probability of fixation is greater than under drift alone. If \(U\) is closer to 1/2 than is \(p\), this results in an increased variance in response (Fig. 1). For example, if \(p = 0.1\), then under drift \(\text{Var}(R) = 4a^2 p (1 - p) = 0.36a^2\). However, if selection increases the probability of \(Q\) being fixed to \(U = 0.4\), then \(\text{Var}(R) = 0.96a^2\). As selection on \(Q\) becomes stronger, the variance in response becomes significantly less than that under drift alone. Conceptually, this makes sense in that, if selection makes it likely that most favorable alleles are fixed, then there will be little variation between replicate lines in the alleles that are fixed. Consequently, when there is strong selection on the underlying loci, there is little to be gained by crossing and reselecting replicate lines.

**COMPUTING \(U\), THE PROBABILITY OF FIXATION UNDER DRIFT AND SELECTION**

To obtain the probability \(U\) of fixation of allele \(Q\), we need an expression that relates \(U\) to fitness on genotypes and an expression relating how selection on a character translates into fitness at the underlying loci. Suppose the fitness and character values are:

<table>
<thead>
<tr>
<th>Genotype</th>
<th>(QQ)</th>
<th>(Qq)</th>
<th>(qq)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fitness</td>
<td>1 + 2(x)</td>
<td>1 + (s)</td>
<td>1</td>
</tr>
<tr>
<td>Character value</td>
<td>1 + 2(a)</td>
<td>1 + (a)</td>
<td>1</td>
</tr>
</tbody>
</table>

For these fitness, Kimura\[^{[3]}\] showed that if \(Q\) starts at frequency \(p\), its probability of fixation is:

\[
U = [1 - \exp(-4Np)]/[1 - \exp(-4Ns)]
\]

(3)

where \(N\) is the population size and \(\exp(x)\) is the exponential function, \(e^x\). If \(4N|s| \ll 1\), \(U=p\), and the allele behaves as if it is neutral.

It remains to obtain \(s\) as a function of the selection on the trait and the effect of the individual alleles. For a locus underlying a trait under selection, the associated selection coefficient \(s\) is approximately:

\[
s = (a/\sigma_z) i
\]

(4)

\(\sigma_z\) is the square root of phenotypic variance of the trait and \(i\) is the selection intensity on the character (e.g., if the
upper 20%, 10%, or 5% of the population is saved, \( i = 1.4, 1.7, \) and 2.0). Details are given in Walsh and Lynch.[4]
Thus \( U(p) \) only deviates significantly from \( p \) when 
\[
2N(1-p)(a/\sigma_z)i
\]
is significantly large. If the product of population \( (N) \), individual allelic effect \( (a/\sigma_z) \), and selection \( (i) \) on the trait is small, the allele is largely controlled by drift. Using Eqs. 3 and 4, the fixation probability of a favorable allele will exceed 0.7 when:

\[
N|i|p(\sigma_z/a) > 0.5 \tag{5}
\]
Thus if the product of initial allele frequency and standardized allelic effect \( (a/\sigma_z) \) is small, many favorable alleles will be lost. Conversely, if Eq. 5 holds, most favorable alleles are fixed, and the resulting variance in response is small. In such cases, crosses between replicate lines are unlikely to generate significant additional variation for subsequent selection.

THE EFFECTS OF MUTATION

In addition to the variance introduced by drift, additional variation is continually generated by mutation. Let \( V_M \) denote the amount of variation introduced in each generation by mutation. Under a pure drift model, the increase in between-line variance from drift for lines separated for \( t \) generations approaches \( 2tNV_M \), which can be substantial. Thus crosses between replicate lines that have been separated for long periods can show considerable potential for additional response. Hill[5] examines the expected divergence when selection on the underlying loci is strong relative to drift.

CONCLUSION

Considerable variation between the performance of selected replicate lines is expected from both drift and mutation. If selection on any underlying locus is small, considerable variation in response is expected. Crosses between such replicate lines generate significant genetic variation for further selection. If selection is strong on each underlying locus, there is little between-line variation, and selection on crosses between the lines is not expected to result in significant improvement.

INTRODUCTION

The haploid male gametophytes of higher plants play a vital role in plant fertility and crop production through the generation and transport of the male gametes to ensure fertilization and seed set. There has been an evolutionary tendency toward reduction of the male gametophyte and its increasing functional dependence on the sporophyte. This trend is most acute within flowering plants, such that the male gametophyte consists of just two or three cells when shed as pollen grains. Despite its diminutive form, the functional specialization of the male gametophyte is thought to be a key factor in the evolutionary success of flowering plants through mechanisms that promote rigorous selection of superior haploid genotypes and outbreeding.

This article describes the sequential phases of angiosperm pollen development—microsporogenesis and microgametogenesis—emphasizing the vital role of the cell wall interface and sporophytic-gametophytic interactions. This article further describes recent progress in genomewide studies of haploid gene expression, genetic approaches that are being used to identify genes required for key cellular processes, and aspects of pollen biotechnology in crop improvement.

POLLEN DEVELOPMENT: FROM MICROSPOROCYTE TO MATURE POLLEN

Microsporogenesis and microgametogenesis take place inside the anther loculi that are lined by the tapetal cell layer (tapetum). Microsporogenesis is initiated upon meiotic division of the diploid pollen mother cell (microsporocyte) that produces four haploid microspores composing a tetrad[1,2] (Fig. 1). During microgametogenesis, microspores released from the tetrads undergo cell expansion, cell wall synthesis, asymmetric division, and differentiation of the vegetative and generative cells before partial dessication and release from the anther. The tapetal cells play a major role in pollen development through their contribution to microspore release, nutrition, pollen wall synthesis, and pollen coat deposition. Disturbance of tapetal cell functions usually results in reduced pollen fertility or male sterility through a variety of mechanisms, including arrest of microgametogenesis at the microspore stage or altered pollen hydration through modified pollen coat composition.

Microsporogenesis

A unique feature of the walls surrounding the microsporocytes and newly formed microspores within the tetrad is that they consist largely of callose, a β-1,3-glucan. The callose wall is secreted by microsporocytes before meiosis I and separates the microspores within the tetrad following meiosis II (Fig. 1). Microspores begin to synthesize the first elements of the sculptured outer pollen wall layer (exine), starting with primexine that functions as a template for subsequent exine elaboration. When young microspores are still developing the exine within the tetrad, an enzyme complex (callase) is secreted by the tapetal cells, allowing individual microspores to be released from the tetrads. Correct timing of callase secretion is critical because premature or delayed dissolution of the callose wall results in male sterility.[3]

Microgametogenesis

Once released, free microspores increase in size and their multiple small vacuoles enlarge and fuse into a single large vacuole, occupying most of the volume of the cell. In concert, the microspore nucleus migrates to a peripheral position that is required for the subsequent asymmetric division at pollen mitosis I (PMI)[4,5] (Fig. 1). PMI results in two morphologically and functionally distinct cells—a large vegetative cell and a small generative cell. The generative cell subsequently becomes engulfed within a membrane-bound compartment in the cytoplasm of its vegetative sister. This involves dissolution of the hemispherical callose wall separating the vegetative and generative cells, inward migration, and membrane fusion events. The asymmetric division at PMI is a key determinative event in generative cell fate.[6]
Fig. 1  Schematic diagram illustrating pollen development. (View this art in color at www.dekker.com.)

Fig. 2  Bicellular and tricellular pollen. (A) Bicellular tomato and (B) tricellular oilseed rape pollen-stained with the DNA stain DAPI. Nuclear DNA within the vegetative (V) and generative (G) or vegetative (V) and sperm cells (S) are highlighted. (View this art in color at www.dekker.com.)
In microspores and immature pollen cultivated in vitro, gametophytic development can be switched to a sporophytic pathway by heat stress and/or starvation treatment, leading to microspore embryogenesis and haploid plant formation.\(^2\) Such techniques are routinely applied to accelerate breeding programs through the rapid generation of double haploid plants and selection among large numbers of homozygous lines.

The generative cell undergoes further mitotic division at pollen mitosis II (PMII) to produce the two sperm cells. In tricellular pollen this division occurs within the anther, whereas in bicellular pollen it occurs within the growing pollen tube. Although the majority of flowering plants produce bicellular pollen, many important food crop plants such as rice, wheat, and maize produce advanced but often short-lived tricellular pollen grains (Fig. 2).\(^2\)

During pollen maturation the vegetative cell accumulates considerable carbohydrate and/or lipid reserves that are transient or are stored in the mature pollen grain. Transient reserves are thought to provide metabolites for energy-demanding developmental events such as asymmetric division and pollen cell wall (intine) synthesis. Osmoprotectants including proline also accumulate in mature pollen grains to protect vital membrane and proteins from damage. In mature pollen grains the extensive stores of lipids and polysaccharides are required to supply the extensive demands for plasma membrane and pollen tube wall synthesis.

During dehydration, the final phase of pollen maturation, pollen grains are finally prepared for release from the anthers. This represents an adaptation to survive exposure to the hostile terrestrial environment. The extent of dehydration varies widely in different species; for example, in poplar the water content is reduced to only 6%, maize loses 50%, whereas cucumber pollen remains fully hydrated. The degree of dehydration and the levels of cytoplasmic reserves positively correlate with pollen fitness and viability. Hydrated pollen is very susceptible to dehydration stress and generally survives only a few hours, whereas fully dehydrated pollen may survive for months or even years under certain conditions.

**THE POLLEN WALL—A VITAL INTERFACE**

The unique activities and biological role of the pollen grain are reflected in the unique composition of the pollen wall. The pollen wall and its coatings isolate and protect the male gametophyte and its associated gametes and mediate the complex communication with the stigma surface. The pollen wall consists of an inner intine and outer exine layer. Its synthesis begins at the microspore stage, when the pectocellulosic intine and the primexine are formed. The primexine serves as a matrix for subsequent deposition of sporopollenin. Sporopollenin is a highly resistant biopolymer containing fatty acids and phenylpropanoids; its synthesis involves tight cooperation between microspore cytoplasm and tapetal cells. The exine is not evenly distributed over the pollen grain surface, and regions lacking sporopollenin form apertures that are used as sites for pollen tube emergence. The number and size of apertures and exine patterning are under strict sporophytic control.

The formation of pollen coatings is completed at later stages of microgametogenesis. Remnants of degenerating tapetal cells are deposited onto the pollen grain surface creating the pollen coat. The pollen coat is involved in pollen–pistil signalling, self-incompatibility, pollen hydration, adhesivity, color, and odor. The yellow or purple colors of mature pollen grain results from the presence of both carotenoid and phenylpropanoid compounds. These features, as well as the elaborate patterning of sporopollenin, are highly variable among different plant species. In animal-pollinated species, pollen is often decorated with elaborate structures that facilitate vector adhesion, whereas in wind-pollinated species, pollen lacks such sculpturing or may be decorated with air sacs to increase buoyancy (Fig. 3).

**HAPLOID GENE EXPRESSION**

Development of the male gametophyte is associated with an extensive haploid gene expression program. To date, approximately 150 pollen-specific genes falling into 50 functional classes have been cloned from various species.\(^4,7\) Recent genomewide studies using microarray hybridization technology have comprehensively demonstrated the scale and diversity of haploid gene expression in *Arabidopsis thaliana*.\(^8\) Mature *Arabidopsis* pollen grains express approximately 5000 different mRNA species out of more than 27,000 predicted from the *Arabi-
dopsis* genome. Approximately 40% of these transcripts are predicted to be preferentially or specifically expressed in pollen. Moreover, there is significant overlap between sporophytic and male gametophytic gene expression that reflects the large proportion of genes that are required for basic cellular functions. The most abundant classes of pollen-specific genes are predicted to have functions associated with transcriptional regulation, signal transduction, cytoskeleton organization, and cell wall synthesis. This highlights the importance of these functions for the unique cellular specialization required for pollen differentiation and function.

Interestingly, some of these pollen-specific genes encode proteins representing major allergens, the cause of hayfever and allergic asthma. Recent work has shown that the expression of one class of allergens from ryegrass
pollen can be reduced without significant impact on plant fertility,\[9\] indicating that the genetic engineering of hypoallergenic cultivars is possible.

Pollen-expressed genes have also been classified according to their temporal regulation. In addition to constitutively expressed genes, groups of early genes active in microspores and late genes acting after PMI have been identified. The late-pollen genes and their regulation have been most intensively studied, resulting in the functional dissection of several pollen-specific transcriptional and translational regulatory elements.\[7\]

**GENETIC APPROACHES: MUTANTS AND DEVELOPMENT**

Renewed interest in genetic analysis and the use of the model species *A. thaliana* have had a significant impact on the identification of gametophytic genes controlling pollen development. Successful mutant selection approaches have been devised that involve screening for aberrant pollen morphogenesis or marker-segregation ratio distortion in populations of plants treated with chemical or physical mutagens or by T-DNA or transposon-mediated mutagenesis.\[4\]

Morphogenesis screens have led to the identification of a number of mutants with novel phenotypes that affect processes throughout microgametogenesis (Table 1). These include mutants that disturb asymmetric cell division at pollen mitosis I,\[6,10,11\] division of the generative cell division,\[4,6\] the positioning and structure of the male germ unit,\[12\] and the repression of pollen germination within the anther.\[13\] Among these, the *gemini pollen1* (*gem1*) mutation has been tracked to a microtubule-associated protein with strong similarity to the human chTOG and *Xenopus* XMAP215 family of microtubule-associated proteins that stimulate plus-end microtubule growth.\[11\] The GEM1 protein plays a vital role in microspore polarity and cytokinesis through its involvement in microtubule assembly, and is associated with interphase, spindle, and phragmoplast microtubule arrays.\[11\] Further exciting discoveries are expected to arise from the identification of the mutant genes responsible for other gametophytic phenotypes described in Table 1.

Screening for gametophytic mutants using marker-segregation ratio distortion has also been used to identify genes involved in microgametogenesis and/or postpollination events including pollen germination, tube growth, and guidance to the ovule. These screens have mostly employed T-DNA or transposon insertion populations that harbor dominant antibiotic or herbicide resistance markers. For example, if a DNA insertion inactivates an essential male gametophytic gene, then the ratio of resistant to sensitive progeny will deviate significantly

In the column labeled ‘mutant,’ the numbers in parenthesis refer to individual mutants with the same mutant symbol prefix. ND = not determined.
below the expected 3:1 ratio toward 1:1. A number of tagged mutants have now been identified that affect microgametogenesis, pollen germination or pollen tube growth. Continued effort in screening and the isolation of tagged genes is expected to lead to a sophisticated genetic map of gametophytic proteins that function during microgametogenesis and postpollination events.

CONCLUSION

The quest to achieve a comprehensive description of the cellular, molecular, and genetic events that control pollen development is not only of fundamental interest, but may find application in the production and genetic improvement of crops. Current knowledge is applied in several areas of crop production, including crop yield optimization and hybrid seed production, and in the production of economic products such as honey and pharmaceuticals. The recent progress in mutational and genome-wide analysis now provides enormous potential to develop new strategies for the molecular dissection and modification of pollen development and functions.

INTRODUCTION

In the classical definition, cytokines are humoral factors secreted from the lymphocytes or monocytes of animals, known as lymphokines and monokines or interleukins as a generic term, and they regulate host immune systems. But now, chemokines, growth factors, and antiviral proteins produced by cells from nonlymphoid origins are included in the cytokine family, and more than 40 proteins are listed.

As more molecules are included in this category, their roles have further expanded to cell growth regulation, antiviral activity, cell differentiation of nonlymphoid cells including those in the nervous system, and the epithelial cells.

The clinical use of cytokines is in the treatment field of neoplastic and viral diseases, and interferon \( \alpha \) and \( \beta \), IL-2, and GCSF have been used for the treatment of neoplastic and viral diseases. Other cytokines may have potential clinical use in tissue regeneration, healing, and for autoimmune diseases. Cytokine receptors and antibodies against cytokines may also be used for therapy of diseases caused by disorder of cytokine network systems including autoimmune diseases.

Updated information including protein and structures, biological activity, receptors, and clinical significance are listed in the references.\(^{[1,2]}\)

EXAMPLES OF PLANT-EXPRESSED CYTOKINES

In the initial phase of research, the expression of antiviral cytokines such as interferon \( \beta \) in plants aimed to produce virus-resistant plants, rather than to produce pharmaceuticals. Although the expression of cytokines themselves did not make plants virus-resistant, the introduction of a mammalian 2-5A oligoadenylate system, one of the interferon-induced antiviral pathways, confers virus resistance.\(^{[3]}\)

Examples of cytokines produced in plants using transgenic or plant viral vector systems are listed in Table 1. The activity of plant-expressed cytokines is determined in in vitro bioassays by using corresponding indicator cells or inhibiting virus replication. Expression levels vary from picograms to micrograms per gram of tissue, but higher expression levels have been achieved by plant viral vector systems. Most cytokines contain intramolecular disulfide linkages that are essential for biological activity. Some cytokines form covalently or noncovalently linked homo or hetero di-, tri-, or tetramers. For example, IL-12 is the heterodimer of p35 and p45 and this heterodimerization is essential for its bioactivity, and TNF\( \alpha \) forms a homodimer or trimer. For this reason, their higher structures must remain intact when produced as recombinant polypeptides. In our study, successful expression of biologically active TNF\( \alpha \) in the potato plant cells revealed that recombinant products,\(^{[4]}\) which should be multimeric to exert its functions, can be expressed in plant expression system.

The cleavage of signal peptides and the processing of larger precursors may also be essential for bioactivity. For example, because IL-18 should be cleaved by an intracellular proteinase, the coexpression of the enzyme is essential for producing biologically active IL-18.

We could not detect the expression of bovine IL-2 in transgenic tobacco, when we introduced the cDNA with the deleted signal peptide nucleotide sequence. On the other hand, when we introduced the cDNA fragment of bovine IL-2 containing the authentic signal peptide sequence, the transgenic tobacco plants expressed bioactive IL-2 (Sugimoto, C. and Matsumura, T., unpublished observation). In addition, the Western blot analyses of TNF\( \alpha \)-transgenic tobacco indicated that proper cleavage of signal peptide occurred in plants because the TNF\( \alpha \) band in transgenic plants was found at the same position as that of mature TNF\( \alpha \) molecules produced by human cells.\(^{[5]}\) These results suggested that the signal peptides of cytokine molecules may function in plant and are essential for their expressions.

Although production of bioactive cytokines in plants has been reported, there is no information about whether these plant products are used in clinical studies at present.
ADVANTAGES OF PLANT EXPRESSION SYSTEMS

Natural forms of human cytokines are usually produced using human cells stimulated by induction reagents, such as RNA virus, bacterial lipopolysaccharide, etc., but this production system requires costly cell culture facilities. In addition, safety regulations for animal-derived materials used for animal cell culture such as bovine serum have become a big issue in pharmaceutical industries. Usually, cytokines exhibit their biological activity at the concentrations of nanograms to picograms per milliliter order. [5]

Therefore their production cost per dose will be much lower than that of the antibodies which is required at the dose of micrograms per milliliter order. However, safer and cheaper production systems are still required.

As animal cells can also produce various cytokines and other bioactive molecules responding to stimuli, these byproducts must be removed during the purification process.

Transgenic animal systems are a possible approach to producing human proteins. However, a problem with cytokines is that several human cytokines are also active in nontarget species, and their consistent production in any tissue at high doses may have deleterious effects on the homeostasis of the host animal.

Production in bacterial and yeast expression systems are also possible. However, bacterial or yeast products are unglycosylated, or differently glycosylated from authentic molecules, which may produce different results in vivo if they are injected into the human body. In addition, several cytokines are produced in inactive or insoluble form in bacterial and yeast cultures, and protein refolding or solubilization processes are required to recover bioactive products.

Recently, we investigated whether orally administered human IFNz (HuIFNz) can augment protection against systemic bacterial infection.\(^{[6,7]}\) Daily oral administrations for 6 days of purified natural HuIFNz reduced bacterial burden in spleen and liver from Listeria monocytogenes-infected mice. This effect was observed in the middle phase of L. monocytogenes infection, but not in the early phase of the infection. Effects of oral administration of HuIFNz expressed in potato plant\(^{[7]}\) were also examined in this infection model. Daily oral administrations of extracts of the transgenic potato tuber for 6 days decreased bacterial burden in the spleen. Lower doses of HuIFNz in the extracts (20 IU/mouse/day) exerted a protective effect at almost the same level as the results achieved by the administration of 1000 IU of HuIFNz. This oral delivery method may open a new area in the clinical use of plant-based cytokines.

**DISADVANTAGES OF PLANT EXPRESSION SYSTEMS**

Most cytokines have one or more N- or O-glycosylation sites, and natural molecules are glycosylated. Generally, glycosylation of cytokines does not affect their in vitro activity, but it significantly affects in vivo stability and activity. Plants and mammals differ in the construction of N-glycans. Moreover, plant glycans lack N-acetylneuraminic acid residue, which affects the biological activity of some plant-expressed cytokines. A typical example is erythropoietin (EPO). Unglycosylated EPO produced in bacterial cells does not show any in vivo activity, and tobacco-derived EPO is not effective in vivo probably due to difference in sugar modification in plants.\(^{[9]}\)

As in vivo activity of several other cytokines are reported to be affected by glycosylation,\(^{[9]}\) animal-type carbohydrate modification is required for cytokines used therapeutically. In addition, plant-specific sugar modification such as α1–3 fucosylation and β1–2 xylosylation could alter the in vivo activity of glycosylated cytokines and produce unexpected side effects including an immune reaction to these structures.

**CONCLUSION**

Plant production may be useful for cytokine production with regard to production cost, infrastructure investment, biological safety, and production of fully bioactive forms. Cytokine-producing plants raise concerns about safety. As cytokines are highly bioactive products, environmental contamination or contamination of the food chain may cause serious problems in human and animal health. Therefore guidelines with special consideration for culturing in fields, harvesting, and processing pharmaceutical-producing plants should be established as a matter of priority.\(^{[10]}\)

Management of Bacterial Diseases of Plants: Biological Control

Mark Wilson
The Colorado College, Colorado Springs, Colorado, U.S.A.

INTRODUCTION
While several biological control agents are commercially available for fungal plant pathogens,[1–4] relatively few are available for bacterial plant pathogens. This chapter will discuss the characteristics and applications of two of the more successful commercially available biological control agents, NOGALL™ and BlightBan™ A506, as well as some novel approaches being examined for the control of bacterial speck and bacterial spot of tomato. Finally, the chapter will speculate on the future of biological control of bacterial diseases in commercial agriculture.

COMMERCIALLY AVAILABLE BIOLOGICAL CONTROL AGENTS

Biological Control of Crown Gall
The most successful biological control agent for a bacterium is Agrobacterium radiobacter strain K84, developed for the control of crown gall. Kerr discovered that application of A. radiobacter strain K84 to bare roots or cuttings prior to planting effectively prevented crown gall development. The mode of action is thought, in part, to be production of the bacteriocin agrocin 84. Until recently, in the United States A. radiobacter strain K84 had been available as Galltrol™, supplied as a culture on an agar plate, and Norbac 84CTM, supplied as a liquid suspension. Currently, only Galltrol™ is available[2] (Table 1). Concerns about the lateral transfer of the plasmid that encodes bacteriocin resistance to Agrobacterium tumefaciens, leading to loss of efficacy of the biological control agent, prompted the development of the genetically modified A. radiobacter strain K1026 with a nontransferable plasmid. NOGALL™, the product based on strain K1026 (Table 1), was the first U.S. Environmental Protection Agency (EPA)-approved, commercially available biological control agent based on a genetically modified organism.[2] The success of this biological control agent is evidenced by its longevity in the market and worldwide usage. This success might also be attributed to the absence of alternative control products, the widespread occurrence of the disease, and the production and distribution by small companies. While much of the biological success may be attributable to the application of the organism to the plant, rather than soil, other factors remain unclear. An analysis of such factors might be informative for the development of future biological control agents of phytopathogenic bacteria.

Biological Control of Fire Blight of Pear and Apple
Fire blight of apple and pear, caused by Erwinia amylovora, occurs throughout the pome-fruit production areas of the United States, Europe, New Zealand, and Israel. BlightBan™ A506, based on Pseudomonas fluorescens strain A506[2,5,6] (Table 1), is used widely for fire blight management in California, Oregon, and Washington. This biological control agent is applied to apple and pear blossoms at the start of bloom and colonizes the blossom, preemptively excluding the pathogen.[6] The success of this biological control agent is due to its activity against more than one target pathogen and its compatibility with standard chemical-based practices. In addition to E. amylovora, BlightBan™ A506 also protects blossoms against frost injury, caused by ice nucleation-active Pseudomonas syringae strains, and protects developing fruit against russet, caused by indole-3-acetic acid-producing bacteria. BlightBan™ A506’s compatibility with streptomycin, routinely used in pear orchards for fire blight control, not only provides additive protection,[5] but has also facilitated the adoption of this product by growers. The search for strains superior in efficacy or complementary to P. fluorescens A506 continues. Pantoea agglomerans (Erwinia herbicola) C9-1, registered with the U.S. EPA as BlightBan™ C9-1 (Table 1), is superior to BlightBan™ A506 under certain environmental conditions, and when used with A506 it extends the environmental conditions under which the product is effective. However, P. agglomerans C9-1 is unlikely to be developed commercially due to concerns about taxonomic relatedness to human pathogens. Despite these concerns, two other P. agglomerans strains have been developed...

commercially, as Bloomtime Biological™ and Blossom Bless™ (Table 1), and assuming there are no health issues associated with these products, we may see increasing use of *P. agglomerans* in the biological control of fire blight.

**BIOLOGICAL CONTROL AGENTS IN DEVELOPMENT**

**Biological Control of Bacterial Spot and Bacterial Speck of Tomato: A Model System**

The biological control of bacterial spot, caused by the pathogens *Xanthomonas campestris* pv. *vesicatoria* and *Xanthomonas vesicatoria*, and bacterial speck, caused by *Pseudomonas syringae* pv. *tomato*, has served as a model system for the investigation of different approaches to biological control of foliar bacterial diseases. Interestingly, *P. fluorescens* A506 provided significant control of bacterial speck under field conditions. However, while BlightBan™ A506 is registered for use on tomatoes for frost protection, the level of bacterial speck control was not adequate to justify commercial development for this purpose. Surprisingly, the most effective biological control agent of bacterial speck and bacterial spot was *P. syringae* strain Cit7, an ice nucleation-active strain recovered from citrus. Unfortunately, even the most effective strain provided an average of only ~30% reduction in disease severity. Furthermore, the biological control agents rarely improved marketable fruit yields.

The use of nonpathogenic *hrp* (hypersensitive response and pathogenicity) mutants of pathogens as potential biological control agents has been reported for *Ralstonia solanacearum* and *E. amylovora*. Nonpathogenic *hrp* mutants of *X. campestris* pv. *vesicatoria* and *P. syringae* pv. *tomato* were examined as potential biological control agents of bacterial spot and speck of tomato, respectively. While *hrpA*, *hrpH*, and *hrpS* mutants of *P. syringae* pv. *tomato* provided significant protection against bacterial speck under greenhouse conditions, only the *hrpS* mutant reduced disease in the field and it was not superior to *P. syringae* Cit7. In contrast, the *hrpX* and *hrpG* mutants of *X. campestris* pv. *vesicatoria* provided significant reductions in bacterial spot severity under field conditions, and the *hrpG* mutant was almost as effective as Actigard™, an activator of plant defenses. The mode of action with the *hrpG* mutant appears to be a dramatic induction of local resistance in the host tissues. Whether the *hrp* mutants of *P. syringae* pv. *tomato* do not induce such host resistance or *P. syringae* pv. *tomato* is not as sensitive to induced host resistance mechanisms is not known. However, it is clear that the host response to *hrp* mutants is not universal, as *hrpE* and *hrpB* mutants of *X. campestris* pv. *vesicatoria* were relatively ineffective as biological control agents. Further development of *hrp* mutants therefore will clearly require a greater understanding of host response.

In an attempt to achieve higher levels of control of bacterial spot and speck, different approaches have been integrated. *Pseudomonas fluorescens*-putida 89-B61 applied to tomato seed and roots provided significant protection against bacterial speck and bacterial spot in the field. Presumably, this is through induction of systemic resistance in the host, although the possibility of foliar colonization and direct interaction with the pathogens cannot be excluded. Unfortunately, the combination of foliar-applied *P. syringae* Cit7 and *P. fluorescens*-putida 89-B61 applied to the seed and roots provided greater control than either biological control agent in only a few instances. This failure to achieve additive levels of protection illustrates that it is important to integrate complementary disease control mechanisms and not just complementary control approaches. For example, we speculate that Cit7 may provide protection through induction of host responses; hence if the signal transduction pathways and host responses induced by Cit7 are similar to those induced by the *P. fluorescens*-putida 89-B61, then one would not expect additive effects in disease control.
antagonistic in their activities. Despite spatial separation, if the systemic resistance induced by the rhizobacterium inhibits colonization by the foliar biological control agent, there will be reduced biological control activity. Clearly, integration is neither simple nor guaranteed to provide superior levels of disease control.

Another approach to biological control of bacterial spot of tomato has been developed based on bacteriophages.\textsuperscript{[11]} Agriphage\textsuperscript{TM} (Table 1), a mixture of bacteriophages, against which the pathogen is unlikely to evolve resistance, has been successfully applied for the control of bacterial spot under field conditions in Florida,\textsuperscript{[11]} and this novel product is being adopted by the local growers. It may be possible to incorporate phage into an integrated control strategy against both bacterial spot and bacterial speck, along with rhizobacteria, that induce systemic resistance, or with chemical plant activators.

THE FUTURE OF BIOLOGICAL CONTROL OF BACTERIAL PLANT DISEASES

While there are relatively few chemicals available for disease control, and antibiotic and copper resistance continues to be a problem, losses due to bacterial diseases in the United States and Europe are too small to attract investment by the agbiotech industry. While losses due to phytopathogenic bacteria are significantly greater in developing tropical and subtropical countries, these countries often lack the expertise or funding to develop biological control agents. If developed for diseases such as bacterial spot of tomato, biological control agents will probably be marketed by small companies, such as those that market NOGALL\textsuperscript{TM} and BlightBan\textsuperscript{TM} A506,\textsuperscript{[12]} or produce the bacteriophage mixtures (Table 1).

One of the most promising approaches is the induction of systemic or local host resistance either by living biological control agents, maybe \textit{hrp} mutants or rhizobacteria; bacterial cell components, such as extracellular polysaccharides, lipopolysaccharides, or flagellin; or bacterial products, such as harpin. These approaches will require significant investment in developing an understanding of antibacterial plant responses and the factors triggering them. Such data are now becoming available.

Management of Bacterial Diseases: Chemical Methods

Donald L. Hopkins
University of Florida, Apopka, Florida, U.S.A.

INTRODUCTION

Bacterial diseases of plants are difficult to control when environmental conditions favor the pathogen’s proliferation. Bacterial disease control often requires a combination of management measures including host resistance, sanitation, cultural practices, and chemicals. Copper-based bactericides and antibiotics, primarily streptomycin and oxytetracycline, are commonly (if imperfectly) used in the management of bacterial plant diseases. In addition to disease management with copper bactericides and antibiotics, the future role of plant defense activators in the control of bacterial diseases will be discussed.

ANTIBIOTICS AND MANAGEMENT OF BACTERIAL DISEASES OF PLANTS

With the introduction of antibiotics in human medicine in the 1950s, their potential in plant disease control was investigated. Although many antibiotics have medical and veterinary uses in the United States, only streptomycin and oxytetracycline currently are used on crop plants, but gentamycin is used in Mexico and several Latin American countries, and quinolines, such as oxolinic acid, are used in Israel for fire blight management. However, the widespread occurrence of resistance to copper-based bactericides such as streptomycin often result in less than desirable levels of control (Table 1).

Antibiotics are used on a small proportion of the crops grown in the United States. Antibiotics are expensive; therefore they are used on high-value crops where the cost is not prohibitive. The primary uses are on fruit trees, such as apple, pear, peach, and nectarine, but other minor uses include ornamental trees, floriculture crops, celery, pepper, potato, tomato, and tobacco. Because of high efficacy and low phytotoxicity, streptomycin is the antibiotic of choice in the United States. Where bacterial pathogens are resistant to streptomycin, oxytetracycline is often used. Externally applied antibiotics or copper is not systemic, but oxytetracycline has been injected into the trunks of trees to control diseases caused by internal bacteria or phytoplasmas.

Applications of streptomycin and oxytetracycline to plants account for less than 0.5% of total antibiotic use in the United States. Whereas streptomycin is bactericidal, oxytetracycline is bacteriostatic. In general, these two antibiotics provide effective control of bacterial diseases of plants, but both have major shortfalls. Streptomycin only remains active on plant surfaces for about 3 days and oxytetracycline is active only for about a day. Thus it is essential to make frequent applications of antibiotics throughout the growing season, which often results in the development of resistance to the antibiotic. The use of streptomycin or oxytetracycline reduces the population of antibiotic-sensitive bacteria, thus favoring the increase of antibiotic-resistant bacteria. Resistance can arise by two distinct mechanisms. The most common is by mutation of a chromosomal gene that reduces binding of the antibiotic to the ribosome, resulting in bacterial strains that are highly resistant and stable. The second mechanism involves the acquisition of a plasmid encoding streptomycin-inactivating enzymes, resulting in moderately resistant strains. One strategy to avoid or delay the onset of antibiotic resistance is to not use a single antibiotic continuously. Where registration allows, streptomycin and oxytetracycline could be tank mixed or alternated. In some crops, it may be possible to alternate antibiotics and copper.

The control of fire blight of apple (caused by Erwinia amylovora) accounts for most of the antibiotic use on plant bacterial diseases. As with most bacterial diseases of plants, fire blight management has many components, with antibiotics being only one of them. Sanitation is most important and prebloom copper sprays can also contribute to disease management. In areas where resistance to streptomycin occurs, growers usually switch to oxytetracycline.

The efficacy of these antibiotics for the control of plant bacterial diseases has diminished in many areas because of the development of resistant bacterial strains. Efforts to maintain the effectiveness of antibiotics against human pathogens have led some medical researchers to recommend reduced use of antibiotics. Because of the possibility of the transfer of resistance from plant bacteria to human pathogens, some special interest groups have lobbied for the discontinuation of antibiotic use in agriculture. Whereas streptomycin has limited use and oxytetracycline is not used in clinical settings, other forms of tetracycline are needed in human medicine. Streptomycin and
oxytetracycline remain available for agricultural use, but it appears unlikely that new antibiotics will be developed for bacterial plant disease management.

**MANAGEMENT OF BACTERIAL DISEASES WITH COPPER COMPOUNDS**

Copper-based bactericides, including Bordeaux mixture, cupric hydroxide, copper salts of fatty acids, tribasic copper sulfate, and mixtures of cupric hydroxide and ethylene bis-dithiocarbamates, are widely used to control bacterial diseases of plants with varying levels of success. A study conducted in the mid-1960s indicated that the combination of copper and mancozeb was more effective than copper alone for control of bacterial spot of tomato (causal agent *Xanthomonas campestris* pv. *vesicatoria*) and also has resulted in increased control of other plant bacterial diseases. Premixing the copper and mancozeb a few hours prior to application is believed by some growers to increase the effectiveness of the combination for the control of bacterial diseases.

Copper compounds are protectants and generally require multiple applications to control bacterial diseases. Copper-based bactericides typically are applied every 5–10 days. High concentrations of soluble copper must be present on the leaf surface to penetrate and kill bacterial pathogens, and this is also phytotoxic to many crop plants. Most tree-fruit crops, such as apple and peach, are sensitive to copper, and sensitivity may be cumulative. Thus, in some plants, there are limitations on stages of plant growth at which copper can be applied and on application rates, and this may result in less than desirable disease control. As with streptomycin, the development of bacterial strains resistant to copper bactericides is quite common, primarily because of the horizontal transfer of plasmid-borne resistance genes between bacteria. This often renders copper compounds ineffective. Resistance results from the bacteria producing specific proteins that sequester copper and prevent it from entering the bacterial cell.

**FUTURE PROSPECTS FOR MANAGEMENT OF BACTERIAL DISEASES**

There is a definite need for new, effective controls for bacterial diseases of plants. However, efforts directed toward the research and development of new chemicals for the management of bacterial plant diseases are very limited. With a shortage of effective antibiotics for human diseases, it seems unlikely that new antibiotics will be developed for plants. Also, agrochemical companies are not putting much effort into developing new controls for plant bacterial diseases because the potential market value of plant bactericides is relatively low. This lack of interest on the part of major chemical companies is further exacerbated by the sporadic nature of disease epidemics caused by phytopathogenic bacteria.

The development of disease control chemicals that induce plant disease resistance offers a new approach to field management of bacterial diseases (Table 1). These chemicals include synthetic inducers of systemic acquired resistance, such as acibenzolar-S-methyl, and natural products such as the harpin protein produced by the bacterium *E. amylovora*. These plant defense activators have no direct antimicrobial activity and work...
by inducing plant resistance to bacterial, fungal, and viral diseases.

The plant defense activators are attractive because they offer a different mode of action from other chemicals. They do not act directly on the pathogen, are generally less toxic than most pesticides, and are environmentally benign, thus the required testing for registration by the EPA is less rigorous than for conventional chemical compounds. There is little chance of the eventual development of pathogen resistance to these materials. These nontraditional chemicals have provided some control of bacterial diseases of tomato and pepper.[7,8]

The plant defense activators are not necessarily a replacement for traditional bacterial disease control chemicals, but may be useful in conjunction with conventional pesticides to improve disease control, reduce the effective dosage or frequency of application, or prevent the development of resistance to bactericides.

CONCLUSION

Antibiotics have been, and continue to be, effective for the control of bacterial diseases on the crop plants on which they are used. However, their effectiveness is declining in some cases because of the development of bacterial resistance. New antibiotics are not being developed for plant use. Copper-based bactericides provide effective control of many bacterial diseases of plants; however, the development of bacterial strains resistant to copper is also becoming common. The agricultural chemical industry is putting little effort into the development of new controls for plant bacterial diseases; however, the relatively new group of plant defense activators could offer alternative approaches to the management of bacterial diseases of plants.

Management of Bacterial Diseases of Plants: Regulatory Aspects

Jaap D. Janse
Plant Protection Service, Wageningen, The Netherlands

INTRODUCTION

Because most plant diseases caused by bacteria cannot be controlled by chemicals, they pose a serious threat to important agricultural and horticultural crops through yield loss and trade barriers. Use of uninfested planting material, sanitation at production sites, and other preventive measures have often proved to be inadequate to control bacterial diseases and therefore many governments have implemented regulations to prevent the introduction and spread of new or existing pathogens. The role of quarantine regulations in the management of bacterial plant diseases, the organization thereof in different parts of the world, and their success is the subject of this article.

LONG DISTANCE MOVEMENT OF PHYTOPATHOGENIC BACTERIA

For bacteria, the most important mechanisms of global movement are internationally traded plants, seeds, and plant parts. With new free trade agreements between countries in different parts of the world, the risk of introducing exotic pests is increasing. Furthermore, new, difficult to trace pathways are developing. For example, commercial companies produce basic planting material outside their regions under varying disease management conditions, and then introduce the products into their regions for further propagation and sale. This has led to the introduction of Ralstonia solanacearum race 3, biovar 2 with Pelargonium cuttings from Kenya into Europe and from Guatemala into the United States.

Other possible pathways for the introduction of exotic phytopathogenic bacteria are the use of nonindigenous pollinating insects and biological control agents. For example, it is suspected that Liberobacter asiaticum was introduced into the U.S. state of Florida with parasitoids used for control of the Asian citrus psyllid Diaphorina citri. Indeed, certain biological control agents, including R. solanacearum, used for control of the forest weed Hedygrium gardnerianum in Hawaii, may attack cultivated hosts. Additionally, genetically modified Agrobacterium tumefaciens strains, used for the genetic manipulation of plants, should also be regulated because they may survive in the transformed host.\(^1\)

APPROACHES TO PREVENT INTRODUCTION OF PHYTOPATHOGENIC BACTERIA

Quarantine regulations are mainly aimed at excluding phytopathogenic bacteria from a territory. These may be laws, orders, or decrees that limit the import of plants or plant products and specify the pathogens of interest.\(^2\) More specifically, quarantines facilitate the isolation and inspection of plants and plant products for prohibited organisms. This is only used for small-scale importations or germplasm sent to postentry quarantine stations for breeding or research purposes. The traditional method of controlling the entry of exotic pests, i.e., inspection at the point of import, is not adequate due to latent symptom development and undetectable levels of bacteria on planting materials. If the host plants are not prohibited, then phytosanitary regulations are based on ensuring that the imported plants are symptomless at the point of origin, as certified by the National Plant Protection Organization (NPPO) of the exporting country. An important principle for ensuring that commodities are pathogen-free is the concept of the pest-free area, assigned when a disease has not been observed in a certain country or part of that country. A pest-free area can be created and officially recognized according to international standards, and commodities can be freely exported from it. Similar in concept is the protected zone, that also must be free of a particular bacterium, but must be especially protected from introduction of the bacterium by stricter phytosanitary measures than adjoining areas. Examples of protected zones can be found in Canada and Europe for Clavibacter michiganensis subsp. sepedonicus and Erwinia amylovora, respectively.\(^3\)

If a pest-free area cannot be established or maintained, phytosanitary regulations may allow plants or plant products to originate from a production site that has been free from the particular bacterium for a defined period of time. Quarantine regulations should also include the eradication...
or containment of introduced bacterial pathogens. Additionally, they should be used to ensure the production of healthy planting materials by certification schemes and standard production protocols.\(^{[4]}\)

Other phytosanitary measures applied to host plants include requirements that the previous generation of the plants or seeds of a commodity be free of the pathogen, and that planting materials be tested or subjected to physical or chemical eradicative treatment.\(^{[4]}\) Furthermore, the exchange of bacterial strains from culture collections is subject to greater regulation, mostly at the national level but also through the World Federation for Culture Collections (WFCC). Note that the WFCC also addresses the possibilities that regulations be employed in preventing the use of pathogens in bioterrorism.\(^{[5]}\) It seems unlikely, however, that plant pathogenic bacteria will ever be used as bioterror tools due to their slow and unpredictable mode of action.

**REGULATIONS AS TRADE BARRIERS**

In the Uruguay round of negotiations (1986–1994) of the World Trade Organization, an agreement on Sanitary and Phytosanitary Measures (SPS Agreement) was developed to discourage the use of phytosanitary measures as non-tariff trade barriers. A pest risk analysis (PRA), including statistically sound surveys of pathogens in the areas or countries involved, was established as the basis for developing regulatory measures. The PRA ensures that an organism is not considered a pest to be quarantined without scientific evidence. For example, \(P.\ syringae\ pv. pisi\), causing pea blight, is seedborne, but severe pea blight outbreaks are more dependent on environmental conditions. Therefore, this bacterium has been withdrawn from the quarantine lists of many European countries. However, effort is still needed to remove unimportant pathogens from quarantine lists.

Regulations should be based on thorough knowledge of the incidence of a disease. In many countries, there is insufficient knowledge of endemic pathogens because systematic surveys are rarely done. Radical changes in standard agricultural practices can promote epidemics that are often claimed to be new pathogen introductions. One example of this is bacterial stripe caused by \(Xanthomonas translucens\ pv. translucens\). At low disease incidence, bacterial stripe symptoms are inconspicuous and easily overlooked. The disease is not important in rain-fed cereals in Syria, but outbreaks occurred when irrigation was intensified, and it was thought that seedborne inoculum was responsible for the outbreaks. The introduction of bacteria on planting material should only be concluded when the bacterium is isolated from the suspected tissues. In the case of bacterial diseases this is difficult, because infested planting material may not display obvious symp-

toms, and biochemical and molecular tests may yield false positive results. Pathogen isolation, adequate confirmatory tests, and maintenance of the original samples and isolates should be required in all cases.

**CREATION OF REGULATIONS**

Sovereign states, under the International Plant Protection Convention and the SPS Agreement, have the right and responsibility for preparing phytosanitary regulations to protect themselves against exotic plant pests. In the past, countries prepared their regulations independently, with the consequence that great discrepancies existed between the principles on which the measures were based, and their degree of technical justification. About fifty years ago, the Food and Agricultural Organization (FAO) of the United Nations, the Regional Plant Protection Organizations (RPPOs), and regional economic integration organizations started supporting countries in this task. The Interim Commission on Phytosanitary Measures, established by the IPPC, develops International Standards on Phytosanitary Measures. These standards establish the principles and procedures of phytosanitary measures, ensuring that countries develop their measures consistently and fairly. In addition, most countries belong to RPPOs that coordinate and harmonize the phytosanitary actions of their member countries on a regional basis. With regard to bacterial pathogens, the European Plant Protection Organization (EPPO) advises its members which bacteria should be quarantine pests, dividing them into A1 quarantine pests (those absent from the region and against which all countries are recommended to take phytosanitary action) and A2 quarantine pests (those present in some parts of the region and of concern to only some countries). The EPPO convenes a panel of experts on bacterial diseases that is responsible for developing technical documentation relevant to each of the quarantined bacteria (e.g., geographic distribution, biology, economic impact), pest-specific phytosanitary requirements (measures that should be adopted by countries that wish to export to an EPPO country), phytosanitary procedures (used by the NPPO of the exporting country to ensure absence of the quarantine bacterium), and pathogen-specific diagnostic protocols. The North American Plant Protection Organization (NAPPO) is developing international standards for phytosanitary measures, a list of regulated plant pests including phytopathogenic bacteria (see Tables 1–3), harmonizing pest management programs through the coordination of pest surveillance programs and developing criteria for seed potato certification.

Regional economic integration organizations such as the European Union (EU) are formed to allow countries to collaborate for the economic benefit of all, and the organizations take over activities that were once conducted.

*cSpecies of uncertain taxonomic position. No reference cultures available.
by the individual states. The EU has based its lists of quarantine organisms and their specific phytosanitary measures on the phytosanitary requirements of the EPPO.\[6\] Tables 1–3 show the bacteria that are quarantine pests for the EPPO and the EU, and indicate those that are considered to be quarantine pests for other regional organizations. As internal control measures, the EU has developed special control directives for bacterial brown rot and bacterial ring rot that allow the safe movement of potatoes from parts of the community that have the disease.\[7–9\] These directives are based on scientific data, and detailed methods for detecting latent infections are provided. Measures are also described for determining pathogen distribution, preventing spread, and suppressing and/or eradicating the disease.

**IF QUARANTINE REGULATIONS FAIL**

If phytosanitary regulations fail to stop the entry of a pathogen, the success of efforts to prevent long-term establishment depends on early pathogen detection, accurate diagnosis, and rapid implementation of management strategies.\[10\] Eradication of pathogens is most likely to be successful on small isolated areas, because it is easier to delimit an outbreak and to prevent re-introductions during the eradication campaign. An example is successful eradication of *Xanthomonas axonopodis pv. citri* from Thursday Island, Australia.\[4\] Regulatory eradication actions often fail because of 1) incomplete pathogen eradication; 2) natural reinvasion; and 3) reintroduction through short- or long-distance movement of infected material. In that case, the realistic options are functional eradication or areawide suppression. The problems encountered in eradication campaigns in larger landmasses are illustrated by the history of citrus canker (*Xanthomonas axonopodis pv. citri*) in the United States. Despite an intensive eradication program in the 1930s, the disease got a foothold in subsequent years and researchers now question whether the pathogen can ever be eradicated under Florida’s climatic conditions.\[11\]

Management of Diseases in Seed Crops

Lindsey J. du Toit
Washington State University, Mount Vernon, Washington, U.S.A.

INTRODUCTION

The success of modern agriculture is dependent on a vital seed industry that enables the timely production and distribution of high-quality, pathogen-free seed of high-yielding cultivars adapted to specific geographic regions and methods of production. The value of the world seed market is estimated at $40–60 billion, and the demand for seed is expected to keep pace with the world’s growing population.\[^{[1]}\] The increasingly global nature of the seed industry brings an associated risk of widespread dissemination of seedborne pathogens. As a result, effective disease management in seed crops remains central to the seed industry.

SEED CROP DISEASES

Although management of plant diseases is important for most crops, it is particularly critical for production of high-quality seed. Plant pathogens can reduce the quantity and quality of seed harvested, and many can be seedborne (Fig. 1). A significant proportion of the seed market is associated with worldwide movement of seeds, and seeds are distributed internationally for breeding programs and research purposes. Seeds provide an efficient means of inadvertently disseminating plant pathogens. Numerous examples can be found of plant disease epidemics resulting from the introduction of seedborne pathogens, often culminating in significant economic losses.\[^{[2]}\]

Strategies for Managing Seed Crop Diseases

General strategies for disease management in agriculture are pertinent to seed crops, i.e., exclusion of pathogens from regions of seed production, eradication of pathogens from seed crops, protection of seed crops, alleviation of disease pressure using cultural practices, and incorporation of disease resistance into cultivars. However, seed production is a complex process involving meticulous criteria followed rigorously by seed producers.\[^{[3]}\] Consequently, disease management programs for seed crops can be more complex than for commercial crops, and require integration of the many tools available. The specific strategies selected are influenced primarily by economic factors, ultimately governing the value and amount of seed produced.

The extremely low tolerance for pathogens in seed crops has resulted in specialized areas of seed production in regions where pathogens are unable to establish or usually remain below threshold levels during seed development.\[^{[4,5]}\] In the United States, seed production occurs primarily in the western states where pressure from fungal and bacterial pathogens is reduced by low rainfall and relative humidity. For example, bean seed production occurs in the semiarid regions of Washington and Idaho. Similarly, the mild winters and dry summers of western Washington make this maritime region ideal for production of biennial Brassica seed crops free of black rot (\textit{Xanthomonas campestris pv. campestris}) and black leg (\textit{Phoma lingam}). Crucifer seed crops in Denmark are located in coastal areas where winds ventilate the crops, reducing development of black spot (\textit{Alternaria brassicicola}).\[^{[2]}\] Furthermore, whenever possible seed crops are isolated from commercial crops for disease control. Lettuce seed produced in the San Joaquin valley of California is isolated from commercial crops in the Salinas valley to prevent infestations of aphids carrying lettuce mosaic virus.\[^{[5]}\]

Production of seeds is an energy-intensive process.\[^{[3]}\] Consequently, some plant species become increasingly susceptible to certain pathogens at flowering. Development of leaf spot of spinach caused by \textit{Stemphylium botryosum} is greatly exacerbated in the presence of pollen, necessitating initiation of protective fungicide applications prior to pollen shed in spinach seed crops.\[^{[6]}\] Although \textit{Fusarium oxysporum} f. sp. \textit{spinaciae} causes damping-off of spinach seedlings, symptoms of \textit{Fusarium} wilt in the seed crop are not apparent until flowering. Yield losses in the seed crop can be extensive without ≥10-year crop rotations.\[^{[7]}\]

The duration of the seed crop season may result in a long window of susceptibility to infection or provide opportunities for infection during periods of stress or injury (e.g., winter injury in biennial carrot seed crops). Overwintered biennial and perennial seed crops may harbor pathogens that can spread to neighboring first-year crops. This green bridge effect led to epidemics of the aphid-vectored beet western yellows luteovirus in the beet seed industry in western Oregon.\[^{[8]}\]
Cultural practices can create less favorable conditions for disease development. Crop inspections and roguing of symptomatic plants or alternative hosts of plant pathogens can reduce disease in a seed crop. Crop rotation is essential for managing many plant diseases. The minimum duration of rotation depends on the longevity of specific pathogens, and may range from a few years to >10 years. Planting seed crops in suppressive soils can assist in production of pathogen-free seed, as demonstrated for pea seed crops free of *F. oxysporum f. sp. pisi* in California. Furrow irrigation restricts splash-dispersal of many pathogens compared to overhead irrigation. Increased spacing of plants reduces disease pressure for fungal and bacterial pathogens as a result of increased air circulation. Incorporation of infested crop debris into the soil reduces survival of some pathogens. Fire is used to reduce inoculum levels of certain plant pathogens (e.g., burning of stubble/straw in grass and cereal seed crops).

Foliar applications of fungicides, bactericides, and resistance-inducing chemicals can provide effective management of many plant pathogens in seed crops. The extended season of seed crops, combined with the low tolerance for seedborne pathogens, often necessitates a greater number of pesticide applications than in commercial crops and requires precise timing of applications with periods of increased susceptibility and disease pressure. However, the minor acreage of individual seed crop species impedes attainment of pesticide registrations for seed crops because of the limited returns to pesticide manufacturers. As a result, some states have implemented programs that qualify certain seed crops for non-food, non-feeding status to facilitate pesticide registrations.

Fumigation, and biofumigation using cover crops, can eradicate persistent inoculum of some pathogens, but the former may be cost-prohibitive. Seed treatments provide effective means of eradicating or reducing some pathogens, and can be applied to both the stock and harvested seed. Fungicide seed treatments eradicate seedborne inoculum, inhibit seed-to-seedling transmission of pathogens, or protect emerging seedlings from soilborne or airborne pathogens. Systemic fungicides are valuable for eradication of internal seed infection and protection of subsequent new growth of seedlings. Physical seed treatments (e.g., hot water, steam, or chlorine) can eradicate or reduce inoculum on seeds. The efficacy of seed treatments depends on the degree of internal infection of the seed, the amount of inoculum in a seed lot, specificity of the treatment, and potential phytotoxicity of the treatments.

Plant breeding has successfully introduced disease resistance into many commercial seed crop cultivars. However, resistance may not be available for some pathogens. In hybrid seed crops, resistance may only be present in one of the parent lines, necessitating disease management practices for the susceptible parent. Furthermore, some pathogens have the ability to overcome single-gene resistance, complicating efforts to manage diseases in seed crops using resistance.

Quality control is fundamental to the seed industry. Seed certification programs encompass field inspections and lab assays so that the history of seed lots can be traced. Emphasis is placed on assays for seedborne pathogens, as many can go undetected during field inspections. To be of value, seed health assays must be specific, sensitive, reliable, cost-effective, and rapid. In 1958, the International Seed Testing Association initiated development of standardized seed health assays.
of methods utilized by different laboratories. This can lead to different results, sometimes with significant ramifications regarding international seed shipments. Techniques for detecting seedborne pathogens include visual inspection, incubation on agar or blotters, staining, pathogenicity tests, serological assays (e.g., enzyme-linked-immunosorbent assays), and nucleic acid assays (e.g., polymerase chain reaction assays). Approval of seed lots for shipment may be based on results of seed assays, so rapid turnaround is critical in seed testing facilities. Advances in rapid nucleic acid assays have overcome problems with inhibitory seed-derived compounds, resulting in increasing application of this technology for seed health assays.

CONCLUSION

The new U.S. National Organics Program for certified organic produce states that the “producer must use organically grown seeds,” “may use untreated nonorganic seeds … when equivalent organic varieties are not commercially available,” and seeds “treated with prohibited substances may be used to produce an organic crop when the application of the substance is a requirement of Federal or State phytosanitary regulations.” These standards have increased the demand for organically-produced seed, but have also raised concerns about associated increases in losses from seedborne pathogens because of the limited number of organic options for seed treatment and disease management. Research is needed to investigate alternatives for successful production of pathogen-free organic seed.

The rapid acceleration in worldwide movement of seed can be justification for plant quarantines. However, there is a significant lack of epidemiological research on the economic impacts of specific seedborne pathogens, on which the regulations and quarantines regarding seedborne pathogens need to be based. Consequently, many of a large number of new phytosanitary regulations cannot be justified scientifically and have been interpreted as phytosanitary barriers used only to protect domestic agricultural industries. Epidemiological research is needed to provide a scientific basis on which to implement regulations affecting the global seed industry.

Management of Fungal and Oomycete Diseases: Fruit Crops

Patricia S. McManus
University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

Fruit crops are produced on nearly 50 million hectares worldwide. Fruit plants are susceptible to diseases at every step in their production and distribution, with economic losses occurring at the nursery, in producers’ fields, during storage after harvest, and in the marketplace. As with other crops, the majority of diseases of fruit crops are caused by fungi. Fungi primarily cause fruit rots, leaf spots and blights, and stem cankers. However, several fungal genera affect roots of fruit crops, either individually (e.g., *Armillaria*) or as members of a disease complex (e.g., *Fusarium* and *Rhizoctonia*). Oomycetes (water molds) primarily cause root and crown rots, but can also cause fruit rots (e.g., strawberry leather rot caused by *Phytophthora cactorum*) and shoot blights (e.g., grape downy mildew caused by *Plasmopara viticola*).

Consumers have high standards when selecting produce and usually pass over fruit with blemishes or other imperfections. Thus, there is nearly zero tolerance for diseases that directly affect fruit. Aesthetics are less important for fruit that will be processed rather than grown for the fresh market, but growers almost always receive a lower price for fruit destined for processing rather than the fresh market. Since the middle 1990s, the demand for high-quality fruit grown in accordance with organic standards has increased, and organically grown fruit typically is sold at a premium. While growing organic fruit might appear lucrative, managing diseases without synthetic fungicides can be a major challenge depending on the crop and climate where it is produced.

As with other crops, managing diseases of fruit depends on manipulating the host, pathogen(s), and environment to favor plant health and inhibit pathogen growth and spread. Since most fruit plants are long-lived perennials, disease management presents unique challenges. The roles of host resistance, pathogen exclusion, cultural practices, and chemical and biological control in fruit disease management are presented separately. In practice, however, fruit growers integrate multiple methods to manage diseases.

GENETIC RESISTANCE OF THE HOST PLANT

Genetic resistance of the host is often the most effective, least expensive, and safest way to manage diseases of fruit crops. For most fruit crops there are numerous cultivars that vary in susceptibility to important diseases. However, cultivar choice is driven more by processor standards and/or consumer preference than disease resistance. For example, McIntosh is one of the leading apple cultivars for fresh-market sales in the eastern United States, but it is also one of the most susceptible to apple scab. Desirable horticultural traits, such as size-controlling rootstocks on fruit trees, are often higher priorities than disease resistance for growers. The extent to which growers depend on host resistance depends on the on crop, the disease, and how the fruit will be marketed (e.g., fresh versus processed; conventional versus organic). Although some fruit crop species have been genetically transformed to improve disease resistance, transgenic fruit crops currently are not produced commercially.

PATHOGEN EXCLUSION

Pathogen exclusion (i.e., preventing a pathogen from reaching its host) is not a practical means of disease management for most fruit crops. Fruit plantings are usually established from nursery stock rather than seed. Indexing stock for viruses is standard practice, but indexing is not practical for most fungal and oomycete pathogens. Thus, pathogens are often carried on nursery stock and remain with the plant its entire life.

CULTURAL PRACTICES

Cultural practices are especially effective in fruit disease management because they can simultaneously improve plant health, reduce pathogen populations, make the environment unfavorable for pathogens, and in the case of pruning, permit more thorough coverage with chemical or biological pesticides.
**Site Selection and Water Management**

Annual crop rotation is not an option with perennial fruit plants. Therefore, establishing plantings on suitable sites is essential. Most fruit crops prefer lighter soils with good water drainage. Since oomycete pathogens proliferate in water, good drainage is key in managing diseases caused by oomycetes. Installing drainage tiles is sometimes necessary in heavier soils. At the other extreme, too little water can stress woody plants and exacerbate certain canker and shoot blight diseases. For example, various species of the fungus *Phomopsis* cause shoot dieback or cankers on many different woody fruit crops. Symptoms are usually made worse by drought stress on the host. Trickle irrigation generally is preferred to overhead irrigation, because the latter can contribute to leaf and fruit diseases. However, for crops where frost protection is needed (e.g., cranberry and strawberry in cooler climates), overhead irrigation is used.

**Sanitation**

Removal and destruction of diseased branches, fruit, and other plant debris reduces pathogen inoculum and thereby decreases disease pressure. For tree and vine crops, sanitation is usually accomplished by manually pruning branches and picking mummified fruit. In the case of apple scab, removing leaves from the orchard floor or shredding them to accelerate their decomposition significantly reduces apple scab inoculum. In perennial strawberry production, leaves are mowed from plants and then either removed from the planting or incorporated into the soil to reduce inoculum of fungal leaf spot pathogens. Cranberry beds are flooded either after harvest or in early spring to remove leaf debris and mummified fruit that harbor fungal fruit rot pathogens.

**Air Movement**

Fungal pathogens of leaves and fruit depend on free water and/or high relative humidity for germination and growth. Any practice that reduces the length of time that foliage and fruit are wet is likely to hinder disease development. Pruning of woody fruit plants, done primarily for horticultural benefits and sanitation, also improves air circulation and drying of foliage. Planting strawberry and raspberry rows parallel to the direction of prevailing winds enhances drying of foliage and fruit. Controlling weeds also reduces the duration of wetness in the lower parts of fruit plants. This is particularly important for cane and bush crops (e.g., raspberry and blueberry), because lower stems are prone to infection by canker-causing fungi.

**CHEMICAL CONTROL**

Under some conditions, diseases of fruit crops can be managed by integrating host resistance and cultural practices. However, most fruit have at least one disease caused by a fungal or oomycete pathogen that requires application of a chemical fungicide. Because fungi and oomycetes are very different biologically, different chemicals are used to control them.

**Chemical Control of Fungi**

Synthetic fungicides commonly used on fruit crops include captan, mancozeb, and chlorothalonil. These are broad-spectrum fungicides that prevent spore germination on the surface of the plant. Nonsynthetic fungicides, such as sulfur and copper compounds, also protect plants from infection and are permitted for use in organic production. Synthetic fungicides are often easier to use and more effective against a range of diseases than sulfur or copper. Nevertheless, sulfur and copper are relatively inexpensive and are highly effective in some situations. For example, under dry conditions powdery mildew may be the only disease that develops, and sulfur is very effective against powdery mildew pathogens of fruit crops.

The sterol demethylation inhibitor (DMI) fungicides (e.g., myclobutanil, fenbuconazole, and tebuconazole) prevent infection but are also taken up by leaves and can kill fungi after infection has occurred. Infection prediction systems are available for some important diseases of apple, grape, and cherry; applying DMI fungicides on a post-infection basis has greatly reduced the amount of fungicide applied to these crops. However, infection prediction systems have been developed and validated for relatively few diseases of fruit crops. Also, after many years of use, some fungal pathogens have become less sensitive to the DMI fungicides, and their ability to eradicate fungi after infection may be compromised.

The relatively new strobilurin fungicides (e.g., azoxystrobin, kresoxim methyl, and trifloxystrobin) have a broad spectrum of activity and are relatively nontoxic to applicators, consumers, and the environment. Use of strobilurins on fruit is increasing but with caution, since fungicide resistance is a concern with this class of fungicides.

**Chemical Control of Oomycetes**

Chemical control of oomycete diseases, especially root and crown rots, is not as effective as good soil drainage. Delivering the chemical to underground plant parts is difficult, and resting spores of oomycetes can withstand chemicals. Moreover, once symptoms of crown rot are detected, the damage is often too great to be mitigated by chemical treatment. However, chemical treatment at the
time of planting can assist root establishment. In established plantings, chemicals are applied in the spring and fall when oomycete pathogens are most active. Mefanoxam is applied directly to soil in enough water to reach roots. Depending on the crop and disease, fosetyl-aluminum is applied to roots as a preplant dip, tree trunks as a wound paint, or leaves, where it is taken up and transported to roots.

**BIOLOGICAL CONTROL**

Biological control of fruit diseases has been researched extensively, but few products are commercially available. The bacterium *Pseudomonas syringae* and the yeast *Candida oleophila* are used as postharvest treatments on citrus and pome fruits to prevent rots caused by *Botrytis cinerea*, *Penicillium* spp., and other fungi. Strains of the fungus *Trichoderma* are used in greenhouses and nurseries to protect roots from both oomycete and fungal pathogens. The fungus *Ampelomyces quisqualis* is a parasite of powdery mildew fungi and is registered on several fruit crops. The bacterium *Bacillus subtilis* suppresses fungal diseases of many fruit crops. Biological control products have not gained widespread acceptance by fruit growers, because they are often less effective against a range of diseases and more expensive than conventional fungicides.

**CONCLUSION**

Fruit crop disease management is accomplished primarily by integrating host resistance, cultural practices, and chemical control. Concerns regarding the negative effects of fungicides on farm workers, consumers, and the environment have spurred the development of safer fungicides and biological control products. Likewise, non-chemical disease management practices are becoming more important because of the high cost of chemicals, restrictions on their use, and the emergence of fungicide-resistant pathogens. Compendia summarizing diseases of the major fruit crops are published by the American Phytopathological Society.[3]

INTRODUCTION

The aesthetic, ecological, and recreational value of turfgrass is immeasurable. Unfortunately, vast expanses of turfgrass are also susceptible to weed invasion, insect infestations, and disease. Integrated pest management (IPM) or integrated disease management (IDM) strategies based on the use of genetic host resistance, cultural practices, chemical applications, and biological control provide environmentally attractive alternatives to the sole and routine use of pesticides. The goals of this entry are to: 1) highlight some of the unique characteristics and complexities of turfgrass cropping systems; 2) identify the major turfgrass diseases and pathogens; and 3) provide an overview of an integrated approach for the management of turfgrass diseases.

WHY TURFGRASS TURNS BROWN

The main reasons for brown turfgrass are adverse environmental factors such as “poor” soils, unfavorable climatic conditions, excessive wear, and improper maintenance. Turfgrass pathogens and pests, alone or in tandem with abiotic factors, also significantly impact turfgrass quality. Although turfgrass managers can do little to influence regional weather patterns or regulate the amount of play or use on a given sward of turfgrass, they are entirely responsible for the management practices they employ. Maintenance practices that favor turfgrass growth over pathogen activity often lead to significant reductions in disease pressure and are considered the foundation of effective turfgrass disease management programs (Fig. 1).

Most turfgrass diseases are caused by fungi and fungal-like organisms (Oomycetes). One convenient, albeit not absolute, way to classify turfgrass diseases is to do so based on the part of the plant being attacked (i.e., foliar diseases, foliar and crown diseases, crown and root diseases). Table 1 lists the major turfgrass diseases caused by fungi and Oomycetes. There is only one economically important turfgrass disease caused by a bacterium [bacterial blight of annual bluegrass (Poa annua)] and of some creeping bentgrass (Agrostis stolonifera) cultivars caused by Xanthomonas campestris] and one disease caused by a virus (St. Augustinegrass Decline caused by Panicum mosaic virus). Nematodes may also cause significant losses in turfgrass, especially in tropical and subtropical climates; however, their impact on cool-season turfgrasses in temperate regions is less well understood.

COMPLEXITY OF TURFGRASS CROPPING SYSTEMS

Although the management of turfgrass diseases is similar to managing diseases of other crops, there are several unique characteristics of turfgrass cropping systems that must be considered before an effective disease management program can be developed. First, turfgrass is a perennial crop whose “yield” is measured in terms of how well it withstands use (i.e., playability of athletic fields or golf-course putting greens) and/or aesthetics (color, density, and overall visual quality) rather than in bushels per acre. Second, most turfgrass areas or swards represent mixed stands of multiple species, cultivars, or both. The situation is even more complex because most turfgrass species are composed of synthetic cultivars made up of co-populations of genetically diverse individuals that often segregate over time based on the influence of abiotic and biotic factors. Older creeping bentgrass putting greens typically show this type of segregation.

Third, turfgrass is used in many different ways (i.e., athletic fields, golf courses, home lawns, roadside ground cover, grassy waterways, etc.) and typically require individualized management approaches. Golf courses are inherently complex turfgrass cropping systems because different turfgrass species/cultivars and maintenance practices are used for different functional areas (i.e., putting greens, fairways, roughs, tees, and clubhouse surroundings). Finally, high-value turfgrass systems such as golf-course putting greens and professional athletic fields are intensively managed (i.e., daily mowing, irrigation, core aeration, topdressing applications, painting, etc.), and although frequent manipulation allows for timely intervention, it can also lead to increased wear and the predisposition of turfgrass to environmental and...
INTEGRATED TURFGRASS DISEASE MANAGEMENT

As pressures mount to reduce inorganic fertilizer and pesticide inputs on turfgrass, interest has increased regarding the development and use of IPM programs that either forego or limit the use of fungicides. Although voluntary in some situations, fungicide use is prohibited or strictly regulated in other situations such as in the case of home lawn or residential turfgrass disease management. Thus a significant push is underway to develop, adopt, and use IPM strategies for managing turfgrass diseases.

The first line of defense to preventing or minimizing disease is through the selection and/or use of disease-resistant turfgrass species/cultivars and the use of pathogen-free certified seed. Information regarding disease-resistant turfgrass may be obtained by contacting local turfgrass seed distributors, extension specialists, and via the National Turfgrass Evaluation Program. The use of genetically resistant turfgrass is limited to newly established or renovated turfgrass areas or in situations where overseeding is used. The second line of defense against turfgrass diseases is the use of cultural management practices designed to optimize turfgrass growth. Cultural practices related to site and seedbed preparation prior to establishment are of paramount importance especially for seedling and root diseases such as damping off and necrotic ring spot. Sand-based root zone mix considerations for putting greens and athletic fields are equally critical. Under certain situations, it may be possible to modify substandard soil conditions under existing swards through the use of core aeration and organic matter topdressing programs.

Disease management in established turfgrass swards is often achieved by modifying cultural management practices such as mowing, watering, fertilization, tree pruning, topdressing applications, and core aeration. As mentioned previously, intensively managed turfgrass is often more predisposed to environmental and biotic stresses, and so it is crucial that agronomic practices be timed to optimize turfgrass growth and, if possible, minimize pathogen activity. To accomplish disease reductions through modification of cultural practices, intimate knowledge of...
the major turfgrass pathogens (listed in Table 1) and the diseases they cause is required. Specifically, those practices which influence the temperature, moisture, and fertility status of turfgrass have been shown to have the greatest impact on turfgrass disease development.\textsuperscript{[5–8]}

Fungicide applications are generally not justified when the primary cause of turfgrass decline is environmental stress. Fungicide applications are often essential where there is a demand for high-quality turfgrass during environmental periods that favor pathogen growth. Fungi-
cides are typically more effective when applied prior to the onset of disease symptoms (referred to as preventive or preventative applications)—this is especially true for crown and root pathogens. Some fungicides are effective when applied after the onset of symptoms and are said to have curative activity. In either case, fungicides must be delivered to the area of the plant where the pathogen is active to be effective. Numerous on-line extension-outreach resources exist that provide specific fungicide recommendations.\textsuperscript{[9]} Always read and follow label recommendations when applying pesticides.

Several recent advances in the use of biological control strategies to manage turfgrass diseases have been reported (i.e., the application of composts and antagonistic microbes); however, relatively few products are commercially available that provide consistent and predictable reductions in disease.\textsuperscript{[3,4]}

**CONCLUSION**

In summary, disease management strategies must be considered in concert with key agronomic practices such as fertilization, mowing, and irrigation as well as other weed and insect pest management efforts. The keys to the effective management of turfgrass diseases are to: 1) be knowledgeable about the turfgrass species/cultivars being managed and the diseases for which they are susceptible; 2) identify well-defined acceptability and risk thresholds for each pathogen; 3) identify all budgetary, use, and other limitations that my influence one’s ability to implement an integrated management plan; 4) develop an integrated turfgrass health management plan taking into consider-
ation possible or anticipated interactions/conflicts with existing agronomic and pest management practices; and 5) implement the plan, modifying as required to attain desired outcomes.

INTRODUCTION

The vegetable crop industry is unique and complex. A diversity of plants and production techniques, as well as growing and marketing operations, make the management of vegetable diseases caused by fungi and oomycetes particularly interesting and challenging. The occurrence, spread, and severity of vegetable diseases, and consequently their management, often hinges on the cropping situation in question.

VEGETABLE PRODUCTION

There are hundreds of different types of traditional and specialty vegetables for which edible plant parts (e.g., roots, tubers, bulbs, stems, leaves, flowers, fruits, or seed) are consumed. Vegetables may be grown in home and market gardens, on small truck farms or large farms, or in greenhouses. Production schemes under various climates range from multiple plantings grown sequentially during the same year to annual cropping under rain-fed conditions or irrigation in arid regions. In some cases, crops are hand-planted or direct-seeded; in others, they are hand- or machine-harvested. Marketing schemes for both domestic and export markets affect handling, storage, and packaging practices, and may involve fresh market sales to consumers, retailers or wholesalers, or advanced contracts with processors. All of these factors influence the types of diseases prevalent in specific vegetable crops, as well as the management tools available to specific vegetable producers.

PRINCIPAL PATHOGENS

The number of plant pathogenic fungi and oomycetes affecting various vegetable crops make for hundreds of vegetable diseases. Key diseases are listed in Table 1, although many more comprehensive indices are available. Vegetable pathogens can be either seed-, soil- or airborne, initiating diseases that are monocyclic (one disease cycle per growing season) or polycyclic (many disease cycles per growing season). Examples of monocyclic diseases are root rots and wilts, where thick-walled resting structures or spores in the soil or decomposing diseased plant debris provide primary sources of inoculum. New spores usually form only toward the end of a growing season, and disease increase is slow but steady over time. In contrast, many foliar diseases such as mildews, leaf spots, and blights are polycyclic diseases. The primary inoculum is often a sexual spore or fruiting body that can withstand adverse environmental conditions. Numerous asexual spores produced on infected plants provide secondary inoculum. These spores are mostly short-lived, but are typically airborne and spread rapidly by wind and rain to cause multiple infections during the growing season.

APPROACHES IN MANAGEMENT

Generally, plant disease control is directed at excluding a pathogen from a particular host or location, eradicating or destroying a pathogen, or offering protection against a pathogen by manipulating the environment or providing some type of effective barrier. Disease controls directed toward improving the resistance of a host or utilizing microorganisms to reduce a pathogen population are also used. Regulatory, cultural, biological, physical, and chemical measures provide the means for accomplishing plant disease control.

Some examples of the exclusion of vegetable pathogens include: 1) bean seed grown in the arid western states of the United States to avoid anthracnose; 2) cabbage transplants inspected before shipment to production fields to manage black leg; and 3) potato seed tubers certified to limit spread of Fusarium and Verticillium. The eradication of pathogens is often accomplished through sanitation practices. Hot water treatments eliminate Septoria from celery, Phoma from cabbage, and Alternaria from carrot seed. Crop hygiene (i.e., the use of disease-free planting material and removal of infected plants) mitigates other inoculum sources. Planting healthy seed tubers and destroying volunteer potato plants that harbor late blight are examples of crop hygiene. Sodium hypochlorite, quartenary ammonium compounds, and other disinfect-

*From Ref. 2.*
Use of vegetable cultivars with genetic resistance results in fewer fungicide applications, and is widely employed. Rust-resistant asparagus, *Fusarium* - and *Verticillium*-resistant tomato, angular leaf spot-resistant cucumber, powdery mildew-resistant squash, and downy mildew-resistant lettuce cultivars are among those that are widely available commercially. However, new races of pathogens often pose the threat of overcoming such resistances, and must be monitored carefully.

Biological control agents are becoming more commonly available in vegetable disease management. They provide useful management alternatives, especially for organic production systems. *Trichoderma, Gliocladium, Streptomyces*, and *Bacillus* spp. are now packaged in commercial products directed mainly at seed- and soilborne pathogens.

Integrated pest management (IPM) programs embrace the principle of integrating multiple crop protection practices to assure minimal pesticide use. By employing genetic, cultural, and biological strategies, and by monitoring pathogen population levels in relation to crop damage, established environmental or pathogen thresholds can serve as guides for appropriately timed chemical applications. IPM programs such as BOTCAST for onion botrytis leaf blight, TOM-CAST for tomato early blight, and BLITE-CAST for potato blight have been used in vegetable disease control.

**CONCLUSION**

Producing healthy vegetables for a growing population with changing food habits will invite new approaches for managing vegetable diseases in the future. The demand for farm-fresh produce, new alternative specialty vegetables, organic production methods, food that is safe from microbial contaminants and pesticide residues, and food grown under production practices that protect the environment may change the ways in which many vegetable diseases are currently managed. Lack of sufficient farmland to ensure adequate crop rotation schemes, compounded by new strains of pathogens with resistance to commercially desirable cultivars or widely used fungicides, may result in the reemergence of vegetable diseases previously kept adequately in check.

To meet such challenges, the availability of more information-based prediction systems may reduce unnecessary fungicide applications and promote more widespread use of biological controls. Novel integration of management strategies (e.g., combining soil solarization and biological agents, utilizing organic amendments in culture media to improve soil quality and control root diseases in transplant operations, and exploiting plant growth-promoting rhizobacteria to induce systemic disease resistance) may be further exploited. Adapting new fungicides with novel modes of action and compounds that trigger defense mechanisms in plants are on the horizon. Expansion into the areas of biologically intensive IPM, computer and video technology, and biotechnology will likely bring about new vegetable disease control measures that are unavailable today.

Management of Nematode Diseases: Options

Gregory L. Tylka
Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

Plant-parasitic nematodes reduce both the quantity and quality of yield produced by grain, fruit, and vegetable crops and cause discoloration and deformation of plant parts sold for fresh market purposes (Fig. 1). Additionally, many modern, large-scale crop production systems rely on uniform growth and maturation of the crop for efficient mechanical harvesting, and parasitism by nematodes can result in uneven development of plants throughout a field or seed bed, reducing harvest efficiency. Plant-parasitic nematodes in the class Adenophorea also serve as vectors for damaging plant viruses. Consequently, there are direct and indirect yield losses that result from plant-parasitic nematode infestations.

The objective of most nematode management programs is reduction in population densities of the targeted nematode(s), resulting in a direct, concomitant increase in crop yield. Such successful management programs not only increase the short-term economic value of crops being grown, but also maintain the future economic value of the land by maintaining productivity through reduction in pathogen population densities. Successful nematode management also may serve to reduce or eliminate indirect yield losses caused by resistance-breaking pathogen interactions and other disease complexes. For example, tomato cultivars possessing genetic resistance to Fusarium wilt, caused by the fungus Fusarium oxysporum lycopersici, will develop the disease if also infected with the root-knot nematode, Meloidogyne incognita.[1] However, use of tomato varieties with genetic resistance to both Fusarium wilt and root-knot nematode results in control of both diseases.

There are numerous strategies or tactics that may be used to manage infestations of plant-parasitic nematodes. However, not all strategies are available for every combination of nematode and host crop. Also, most nematode management strategies are not therapeutic; they must be implemented before the crop is planted. Consequently, growers must have advance knowledge of the presence of damaging population densities of nematodes in the fields where crops will be grown. To develop an effective management program for plant-parasitic nematodes, growers must consider what management tactics are available, the economic costs of those tactics in relation to the value of the crop being grown, and whether the management tactics can be implemented without disruption of the production system. There are several categories of nematode management strategies.

EFFECTIVE SCOUTING AND IDENTIFICATION

The first step in a successful nematode management program is accurate and early identification or diagnosis of a problem. However, obvious symptoms of damage may not appear for many months or years after a nematode infestation becomes established due to the obligately parasitic nature of plant-parasitic nematodes (Fig. 2). Extension educators and agribusiness personnel (agronomists, crop scouts, crop advisors, etc.), who routinely communicate and interact with growers, are essential in the development of a nematode management program. These individuals often are the first to notice unusual growth patterns in the crops and usually are knowledgeable about appropriate techniques for scouting for plant-parasitic nematodes, as well as other types of pests. Also, these people often assist growers in determining what specific management tactics are deployed.

Effective scouting for plant-parasitic nematode infestations involves careful observation of plant parts for disease symptoms, but confirmation of a nematode infestation usually requires collection and analysis of plant and/or soil samples. Identification of the genera of plant-parasitic nematodes and enumeration of the number of individuals present is often sufficient for diagnosis and subsequent development of a management program. However, identification of plant-parasitic nematodes to species or subspecific level (race or biotype or pathotype) is necessary in some cases. Accurate knowledge of the nematode or nematodes causing damage is essential in defining what tactics will be effective in a management program. For example, the geographic range of numerous species of the lesion nematode Pratylenchus overlap, but the host ranges of the species can vary considerably.[2] Consequently, if a grower wanted to grow a crop that was not a host for the lesion nematode...
present in a field as part of a management program, it would be necessary to determine the species of *Pratylenchus* present in order to know what crop species will not serve as a host for the nematode. In addition to host range, other aspects of the biology of the nematode that influence the effectiveness of various management options include the length of the nematode life cycle, the reproductive capability of the nematode females, and the ability of the nematode to survive periods of adverse environmental conditions (i.e., temperature extremes, lack of water, lack of food).

**HOST RESISTANCE**

For many crops and species of plant-parasitic nematodes, host resistance is an effective and economic management strategy. Nematode resistance is defined as a plant allowing only inefficient reproduction of a nematode species. Because reproduction of the nematode is reduced on resistant plant cultivars, the quantity (and possibly quality) of yield is usually increased, and a reduction in nematode population densities during the course of a growing season usually occurs. Host resistance to plant-parasitic nematodes has been identified and incorporated into many grain, fruit, and fiber crops, and resistance is mostly to sedentary, endoparasitic nematodes, which have a complex feeding relationship with their hosts. Although host plant resistance to nematodes reduces nematode reproduction, the resistance is usually not 100% effective, and a small proportion of the nematode population can successfully reproduce on the resistant plants. Consequently, repeated use of the resistance can result in directional selection of a nematode population that is capable of reproducing on the resistant plant. Nevertheless, host plant resistance is an effective and economical nematode management strategy that warrants serious consideration when available as a management option.

**HOST TOLERANCE**

In addition to host plant resistance, nematode-tolerant plant cultivars can be a useful management tool. Nematode-tolerant plants are those that are relatively insensitive to parasitism by plant-parasitic nematodes. Tolerant cultivars suffer relatively little yield loss despite being parasitized by nematodes. In addition to providing economically acceptable yields in nematode-infested fields, tolerant plant cultivars can effectively prolong the utility of resistant plant cultivars by not selecting for nematode populations that can reproduce on resistant
cultivars. Unfortunately, nematode-tolerant plant cultivars are not available for most crops.

NONHOST CROPS

Because plant-parasitic nematodes are obligate parasites, they are unable to complete their life cycles and reproduce in the absence of a host crop. Thus, growing nonhost crops can be an effective management strategy. But the usefulness of this management strategy depends on several factors. Most obviously, the host range of the damaging plant-parasitic nematodes targeted for control will dictate what nonhost crops can be utilized for management purposes. There will be only a few nonhost crop possibilities for nematodes that have a broad host range, such as many species of lesion nematode (*Pratylenchus*), whereas there are several nonhost crop options for nematodes that can reproduce on only a few crop plants, such as the soybean cyst nematode (*Heterodera glycines*). Also, use of nonhost crops will not be an option if the nonhost crops are not of sufficient economic worth in the production systems in which the nematodes need to be controlled. For example, the soybean cyst nematode is a widespread and very damaging parasite of soybeans throughout the entire midwestern United States, and this nematode is unable to reproduce on many crop species, but corn is the only nonhost crop that is grown in alternating years with soybeans throughout most of this region because of agricultural economic constraints. Finally, use of nonhost crops as a nematode management strategy is more effective for plant-parasitic nematodes that cannot survive long periods of time in the absence of a host crop than for those nematodes that have effective long-term survival mechanisms, such as the cyst nematodes (*Globodera* and *Heterodera*).

CHEMICAL CONTROL

Beginning in the middle of the 20th century, pesticides became an effective and cost-efficient means to manage many plant-parasitic nematodes. Many such products, with various modes of action, were developed and marketed beginning in the 1940s. These pesticides generally can be categorized based on their physical properties as either fumigants or contact nematicides.[5] Fumigant nematicides vaporize when applied and permeate quickly through the soil. The effectiveness of fumigants is affected by soil factors such as moisture, temperature, texture, and type. Contact nematicides do not vaporize and, consequently, they diffuse more slowly and are not affected by soil factors as much as fumigants. Some of the more common nematicides include those with the common names aldicarb, carbofuran, 1,3 dichloropropene, dimecachlor, ethoprop, ethylene dibromide, fenamiphos, oxamyl, and terbufos.[5,6] Also, broad-spectrum, fumigant biocides used to manage plant-parasitic nematodes include chloropicrin, metam sodium, and methyl bromide.

In the latter part of the 20th century, many nematicides were banned from use in the United States because of environmental concerns. Currently, there are still several nematicidal products registered for use for nematode management, but the legal availability of these products varies greatly depending on the host crop. Nematicides and biocides are an integral part of nematode management programs for high-value fruit and vegetable crops, but very few of these pesticides are still registered for use in the United States for nematode management on low-value row crops and specialty crops grown in relatively small areas. Methyl bromide is widely used for control of insects, weeds, nematodes, and other pathogens in many different crops in the United States, but this biocide is being gradually phased out due to its harmful effects on the Earth’s ozone layer. The use of methyl bromide will be completely discontinued in the United States and other developed countries by the year 2005. Research is underway to identify alternatives to methyl bromide for control of these pests and pathogens.

There are several difficulties associated with chemical control of soil-borne, plant-parasitic nematodes.[6] Crop species vary in their sensitivity to the pesticides used for nematode management, and phytotoxicity is more of a concern with the broad-spectrum biocides than with the nematicides. Additionally, nematodes can be distributed a meter or more down into the soil, so incorporation of the pesticides deep into the soil profile is essential to maximize effectiveness, particularly for those products that are not fumigants. No nematicide or biocide will be able to kill all of the individuals in the targeted nematode population and surviving nematodes usually multiply throughout the growing season, so repeated application of these pesticides every time a susceptible crop is grown is usually necessary. Also, individual nematodes that survive nematicide applications may possess some resistance to the chemicals, so selection for nematicide-resistant nematode populations can be a concern. But despite these practical difficulties, limitations, and concerns, nematicides and broad-spectrum biocides can be effective and economical management tactics for plant-parasitic nematodes for some crop production systems, depending on the value of the crop, the crop production practices that are routinely used, the plant-parasitic nematode species that
are targeted, and the legal availability of the nematicidal or biocide products.

**BIOLOGICAL CONTROL**

There are many organisms that live in soil and utilize nematodes as a food source, including bacteria, fungi, mites, and other nematodes. Several natural antagonists, primarily bacteria and fungi, have been investigated for use as biological control agents for plant-parasitic nematodes. Although results of some experiments indicate that there is great potential for use of such natural antagonists for management of plant-parasitic nematodes, few products have been commercialized and are available currently for use in managing nematodes.

**OTHER TACTICS**

There are many other crop production practices that can be employed in attempts to reduce nematode reproduction and/or increase crop yields. As with most every other management strategy, these tactics will not have a beneficial effect for every combination of nematode and host crop. Among the more common practices that have been employed in attempts to achieve management of plant-parasitic nematodes are: 1) planting earlier or later than normal to avoid peak periods of infection of the young crop by the nematode population, 2) growing nematicidal cover crops and trap crops, and 3) leaving infested areas unplanted to reduce nematode population densities directly. Reducing the movement of soil and infected plant tissue, and thus the movement of plant-parasitic nematodes, from field to field by washing off tillage equipment and using only thoroughly cleaned seed (Fig. 3) and propagation materials that are free of nematode infection can also be of great benefit in a nematode management program. But these various tactics vary greatly in their utility based on the biology of the targeted nematode species and crop plant as well as other aspects of the crop production system. Nonetheless, many such tactics can add to the effectiveness of an integrated nematode management program.

**CONCLUSION**

As is the case with most pests, the most effective management program for plant-parasitic nematodes is one that incorporates several management strategies rather than one that relies on any single tactic. The limitation to integrated pest management (IPM) for plant-parasitic nematodes is the availability of different management tactics, such as host resistance, nonhost crops, and nematicides. Fig. 4 illustrates the recommended program for integrated management of the soybean cyst nematode in Iowa. Coordinated use of all available management strategies serves to reduce the selection pressure on nematode populations to overcome any individual tactic and decreases the risk of failure of any single management tactic.

**Marigold Flower: Industrial Applications**

James N. BeMiller  
*Purdue University, West Lafayette, Indiana, U.S.A.*

**INTRODUCTION**

Marigold (*Tagetes erecta*) is grown commercially as a source of lutein, which is used as a poultry feed additive, a yellow food coloring, and a human nutritional supplement. Lutein is absorbed more efficiently from the gastrointestinal tract when the naturally occurring esterified form is saponified. The spent flower meal after lutein ester extraction yields a protein-polysaccharide with citrus oil emulsifying and emulsion-stabilizing properties. This water-soluble gum, called marigold flower polysaccharide (MFP), has been partially characterized.

**MARIGOLD FLOWER PRODUCTION AND USE**

Marigold (*Tagetes erecta* L., family Asteraceae) is grown not only as an ornamental, cut flower, and landscape plant, but also as a source of lutein for use as an additive to poultry feed, as a yellow food coloring, and as a human nutritional supplement. Marigolds are grown for this purpose in various locations in the Western Hemisphere (primarily in Mexico and Peru) and in Asia, by and for various companies who process flowers into various products. The agronomics of *Tagetes erecta* have been studied rather extensively.

Marigold flower oil, an essential oil obtained by steam distillation, is used for compounding perfumes. The essential oil contains biocidal components (terpenoids) and has been investigated for its bactericidal, fungicidal, larvicidal, insecticidal, and wound healing properties.

**PREPARATION OF LUTEIN**

Blossoms are collected both by hand and mechanically. Fresh blossoms are either heated or ensiled, then pressed to remove as much water as possible. The resulting cake is dried, pelleted, and subjected to extraction, usually with hexane. The extracted pigment, called marigold oleoresin, is primarily composed of mono- and diesters of lutein (88%).

By far the largest volume use of lutein is as an additive to poultry feed. It is added to intensify the yellow color of egg yolks and broiler skin, especially where white corn is used as feed. However, lutein esters, the primary component of the oleoresin, are not absorbed well, so the pigment is usually saponified. Various degrees of purification are used. For poultry feed, crude saponified extract in the form of an emulsion is usually absorbed on a material such as an earth or the meal remaining after extraction, which has been finely ground to convert it into a dry powder. This product has also been added to fish feed. That used as a food coloring or added to vitamin mixtures must be purified. Lutein is an antioxidant that scavenges singlet oxygen and free radicals. It is claimed to prevent age-related macular degeneration[1] and is accepted as a “generally recognized as safe” substance by the U.S. Food and Drug Administration. Marigold oleoresin has been investigated as a dye for silk.

**MARIGOLD FLOWER POLYSACCHARIDE**

Water extraction of the meal remaining after commercial removal of the oleoresin from marigold flowers yields a water-soluble gum called marigold flower polysaccharide (MFP).[2] Low-concentration, aqueous solutions of MFP have low viscosity and exhibit emulsifying and emulsion-stabilizing properties similar to those of gum arabic (gum acacia).[2,3] This is important because there is a desire among food processors and other users of gum arabic (gum acacia) to have an alternative to it, because the supply and quality of gum arabic are variable and uncertain. Gum arabic has unique and important properties and applications.[4] Crucial unique properties of gum arabic are its ability to form high-solids, low-viscosity solutions; its emulsifying and protective colloid properties; its ability to withstand relatively high temperatures during spray-drying; and its adhesive and film-forming properties. It is used in food, beverage, confectionary, and related products. Among its unique and important applications are the preparation of spray-dried, free-flowing citrus oil powders (fixed flavors) and bakers’ citrus oil emulsions, and as a glaze on confectionary products.
MFP can be extracted from spent meal with warm (50–55°C) water. MFP is a heterogenous material. The major component is a protein-polysaccharide as is the active component of gum arabic. The polysaccharide component is a highly branched, acidic arabinogalactan containing D-galactose, D-glucose, L-arabinose, and D-galacturonic acid in approximate mole ratios of 16:6:3:1. The protein part is composed of at least two hydrophobic polypeptide constituents. The structures of gum arabic and MFP (as protein-polysaccharides) are both unique in the world of industrial and food gums (hydrocolloids) and are key to their properties. In commercial gum arabic, the active component—a protein-polysaccharide—comprises only 1–2% of the total material.

As previously stated, aqueous solutions of MFP, at low concentrations, have low viscosity and have emulsifying and emulsion-stabilizing properties similar to those of gum arabic. However, while gum arabic forms low-viscosity solutions at concentrations up to 25%, the concentration at which MFP solutions began to exhibit marked increases in viscosity for small increases in concentration is about 4%. Therefore, it cannot produce high-solids, low-viscosity solutions as gum arabic does.

The crude MFP extract is dark. To obtain minimal color, an oxidative pretreatment of the meal prior to gum extraction was developed. Bleached MFP also has emulsifying and emulsion-stabilizing powers for limonene equivalent to those of gum arabic at equal concentrations. However, the pretreatment increases the viscosity of MFP solutions. Therefore, it is currently not possible to prepare the desired high-solids, low-viscosity solutions of MFP and, hence, the concentrated emulsions. Clearly, this substance warrants further investigation, even though specially modified starch products are acceptable substitutes for gum arabic in many applications.

INTRODUCTION

Proteomics is the large-scale identification and quantitation of the complete set of expressed proteins, defined as the proteome, of the cell. The large number of posttranslational modifications, protein–protein interactions, and subcellular locations make the proteome considerably more complex than the protein-coding capacity of the genome. This article discusses the progress in mass spectrometry in identifying proteins, in protein modifications, and in discovering protein interactions. Not covered here is the progress in other methods.

MASS SPECTROMETRY OF PEPTIDES AND PROTEINS

Mass spectrometry (MS) precisely measures the mass/charge ratio of molecules. Whole protein masses can be measured, but much higher-quality data are obtained by first digesting the proteins to peptides with a site-specific protease such as trypsin. The recent availability of the sequence of most or all of the genome of an organism has revolutionized the interpretation of MS peptide data by allowing the identification of the gene encoding the identified peptide(s).[3,4]

Single-stage MS instruments only measure the peptide’s mass/charge ratio. The resulting precise peptide mass measurements are used to calculate possible amino acid compositions, but not the sequence, of the peptide. If the masses of several peptides from the same protein are obtained, the protein can often be identified from informatics analysis of the masses of the predicted protein’s digested peptides from the sequenced, annotated genome. Tandem MS-MS instruments separate the peptides in an initial MS stage and then fragment them by collision with a heavy gas, and the mass/charge ratio of the fragments are then determined in a second tandem MS stage. This fragmentation pattern can be used to determine the actual sequence of the peptide. The sequence of a single peptide is often enough to identify the gene from analysis of the genome sequence (Fig. 1).

The ability of MS instruments to detect smaller amounts of peptides and proteins has improved substantially,[5] with sensitivity reported in the attomol to femtomol levels. However, the sensitivity is still less than that of DNA techniques because protein technologies still lack two key aspects of nucleic acid technologies: the ability to be amplified directly, as is done with DNA by PCR, and a simple, sequence-dependent detection method analogous to the hybridization of nucleic acids. The lack of a direct protein amplification technology makes the sensitivity of detection by MS critical. The lack of a protein sequence-dependent detection method makes the relative abundance of the protein of interest critical. The net result is that only 10 to 20% of the cell’s proteins can be readily detected in the standard 2-D gel electrophoresis methods. Examination of protein modifications and protein–protein interactions generally requires some additional level of prior purification, either to obtain sufficient amounts of protein for a more detailed MS analysis or to obtain copurification of interacting proteins.

MASS SPECTROMETRY IDENTIFICATION OF PROTEINS

Currently, the standard method of using MS to identify new proteins is to fractionate the proteins by 2-D gel electrophoresis (2DE) to provide sufficient resolution to separate many but not all of the proteins. The protein spots are then visualized by staining with either colloidal Coomassie blue or a MS-friendly silver stain protocol or with some of the newer fluorescent dyes that work well for MS, such as Sypro Ruby.[6] The detection limits of the dyes are generally in the 1–5 ng of protein range, which is sufficient protein for MS analysis. Typically, the 2DE gel patterns of the control and experimental samples are compared by image analysis software to identify individual spots that differ in their expression levels or modification. The protein spots of interest can be picked, preferably by automation, as contamination by skin proteins is a frequent problem. The isolated, protein-containing gel fragments are then chemically modified and
MASS SPECTROMETRY IDENTIFICATION OF PROTEIN MODIFICATIONS

Much of the regulation of protein activity occurs at the level of covalent modifications and protein–protein interactions. Covalent modifications alter the mass of the digested peptide, and there are over 100 known modifications, including the more common ones such as glycosylation, phosphorylation, acetylation, and methylation. The challenge with identifying protein modifications is that it is rare to identify all the peptides in a digested protein due to different rates of vaporization and detection, with 20% coverage of the peptides being more typical. Additional problems are the occurrence of mixtures of proteins and peptides in the fractionation methods, making it difficult to analyze peptides present in low amounts in the mixture. Therefore, relatively pure proteins are currently needed for covalent modification studies to assign the modified or low-abundance peptides to the protein of interest.\(^9\) Purifications can be facilitated with either antibody precipitations or by using the high-affinity protein tags described below.

MASS SPECTROMETRY IDENTIFICATION OF PROTEIN INTERACTIONS

The most common separations techniques prior to MS analysis, such as 2DE, destroy protein–protein interactions and are only useful for detecting individual proteins. Additionally, identifying low-abundance proteins still represents considerable separations and sensitivity challenges for current MS instruments. A new approach, which combines affinity-tagged proteins and MS, provides a high level of purification of intact protein complexes. This new approach creates an in-frame fusion of a high-affinity tag to the gene and then transfers the tagged gene back into the cells or the organism. The resulting affinity tag on the fusion protein provides a standard high-affinity, gentle purification method that allows highly purified samples of the tagged protein and any interacting proteins to be obtained as intact complexes. The high degree of purification also allows for processing the large amounts of starting materials necessary to detect low-abundance proteins.

The affinity-tags used have been designed for either single-step or two-step purifications and rely on the copurification of other proteins to be an indication of protein–protein interactions. In the two-step or tandem purifications, a first affinity purification and elution step is followed by a second, different affinity purification and elution step, providing a much higher level of purification than a single-affinity-step purification.\(^10\) For example, the tandem affinity purification or TAP method\(^11\) uses IgG beads to bind to a protein A domain in the affinity tag, and then releases the bound protein by using a site-specific protease to cleave at its specific recognition site in the affinity tag eluting the now slightly shorter fusion protein. The second purification step uses a calmodulin
binding protein domain in the remaining portion of the affinity tag to bind to calmodulin beads, in a Ca++-dependent manner, followed by elution by chelation of the Ca++ with EGTA. The two-step purification provides a higher level of purification and thus more reliable data on the proteins likely to be interacting with the tagged protein, as opposed to those that fortuitously copurify. Single and tandem affinity tags have been used in analyzing large numbers of yeast protein interactions\(^{12,13}\) but are still relatively new in plant applications.\(^{14}\) In the yeast examples, many of the copurifying yeast proteins found in affinity-tagged protein complexes had been previously identified by genetic or biochemical methods, confirming the validity of the affinity tag method.

It is critical that copurifying proteins are confirmed with additional experiments. The simplest step is to repeat the experiment, as 30% of copurifying proteins are not found again.\(^{12}\) Further confirmation can be obtained by epitope-tagging the new interacting protein and confirming its interaction with the first tagged protein by precipitation of the in vivo complexes and by verifying that both proteins were precipitated by the presence of the second epitope.\(^{15}\) If the function of the tagged gene is known, and therefore provides information about what type of pathway the protein is part of, functionally testing the gene encoding the interacting protein is an excellent method to confirm the interaction, using one of the functional genomics technologies described in this book.

**SUMMARY**

The 2DE approach can be used to identify proteins in any plant, although it is much more efficient when most or all of the genome sequence is known, as this facilitates the identification of the gene encoding the peptide(s) identified. The affinity-tagging methods can be used for any plant into which genes can be stably transformed. Additionally, in some instances transient expression assays can be conducted in cells that have the responses appropriate for the biology being examined, greatly increasing experimental flexibility and speed.\(^{14}\) For example, *Arabidopsis* suspension culture cells can be infected with *Agrobacterium* in sufficient amounts for proteomic analysis\(^{15,16}\) and show responses to osmotic and salt stress. We have recently demonstrated that transient expression of several TAP-tagged proteins that are involved in osmotic stress signaling in *Arabidopsis* cells can be purified in amounts sufficient for tandem MS/MS sequencing of the peptides of the isolated and digested proteins.

The post-genome era will herald increasing focus on gene function and biochemical mechanisms. Proteomics tools, particularly mass spectrometry, will play an increasing role in identifying proteins, their modifications, and their protein–protein interactions. Recent results in protein–protein interactions in yeast indicate that an extensive network of interacting proteins exists in cells that we are only now beginning to understand.\(^{17}\)

Mechanisms of Infection: Imperfect Fungi

Gyungsoon Park
Jin-Rong Xu
Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Imperfect fungi (deuteromycetes) by definition are fungi that do not have known sexual stages. Although their taxonomic status is no longer valid, many of several thousands of known imperfect fungal species are important plant pathogens. In general, infection starts with the adhesion of fungal propagules (usually asexual spores or conidia) to plant surfaces followed by surface recognition and penetration. Some fungi enter plant hosts through natural openings, such as stomata or wounds, while others directly penetrate through plant surfaces and epidermal cells. After penetration, infectious hyphae colonize plant tissues and induce disease symptom development.

ATTACHMENT AND GERMINATION

Attachment

Adhesion of dispersing propagules to plant surfaces is commonly the first step of infection by fungal pathogens, but the composition of the adhesive materials and the development of adhesiveness vary among fungal species. In some fungi, the adhesive materials are preformed and released upon contact with the plant surface or upon hydration of conidia, such as the spore tip mucilage formed by the rice blast fungus Magnaporthe grisea and the adhesion knob formed by the nematode trapping fungus Drechmeria coniospora. In some fungal pathogens, the extracellular matrix of conidia may contain adhesive materials or enzymes that assist in attachment and preparation of the infection court.[3] In fungi with an active adhesion process, respiration and protein synthesis are required before the conidia or their germ tubes become adhesive. Synthesis of adhesive materials may be stimulated by compounds present at plant surfaces or regulated by specific fungal-plant recognition events.[4]

Adhesion has been recognized as an important step in plant infection, and it is worth noting that fungal adhesion can occur at different stages of infection-related morphogenesis.[2] Various proteins, glycoproteins, and polysaccharides have been identified in different pathogens, but the exact chemical components of adhesive materials have not been determined for most fungi. No fungal adhesive compound has been experimentally proved by directed mutagenesis to mediate plant attachment.

Germination

Conidial germination involves activation, swelling, and germ tube emergence.[3] In a few fungi, such as Botrytis cinerea and some Colletotrichum species, conidia can remain dormant or quiescent on plant surfaces until host plants produce certain stimulatory compounds (e.g., ethylene produced during fruit ripening). However, in most fungal pathogens, conidia germinate immediately after attachment and produce germ tubes when moisture, nutrients, temperature, and other environmental conditions are favorable. Conidia of a number of fungi contain endogenous self-inhibitors that prevent conidia from germinating when the spore density exceeds a given threshold. Germination occurs only after these compounds are washed off or diluted, or their inhibitory effects are relieved with nutritional supplements or plant surface molecules (such as cutin monomers). In many fungi, adhesive materials are formed surrounding the germ tubes to mediate adhesion and possibly provide protection against harmful environmental factors.

PENETRATION

Penetration Structures

Fungal pathogens have evolved distinct strategies for penetrating plant leaves, stems, or roots. In some fungi, the undifferentiated germ tube or hyphal tip can directly form a penetration peg to invade plant cells. The penetration peg is a thin, tip-growing cellular protuberance that is generally much narrower than somatic hyphae. However, in many fungi, penetration pegs develop from the thin-walled appressorial pores located at the contact area between the appressorium and the plant surface. Appressoria are infection structures formed on the end of germ tubes or hyphae for adhering to host surface and subsequent penetration. The tight adhesion of appressoria to the plant surface is mediated by a ring of appressorium...
mucilage. An appressorium can be a simple or multiple-lobed germ tube tip swelling or a specialized swollen body delimited from the germ tube by a septum. Some fungi form multicellular aggregates that are known as compound appressoria or infection cushions. Multiple penetration pegs can arise from a single compound appressorium. Penetration pegs also can develop from a net-like mycelium without well-differentiated appressoria. Another infection structure common among asexual foliar pathogens is the hyphopodium. Hyphopodia formed on ephelistic somatic hyphae may be terminal, lateral, or intercalary, simple or lobed. Many environmental factors, including temperature, pH, nutrients, plant surface molecules and physical features, are known to affect penetration structure formation. Germ tubes can also recognize surface hydrophobicity, hardness, components of the plant surface, and topographical properties to regulate infection-related morphogenesis.

Mechanisms of Penetration

Both physical and enzymatic forces are used by fungal pathogens to invade plant tissues.\[4\] In fungi such as M. grisea, elevated osmotic pressures within melanized appressoria are used to puncture leaf cuticles physically and plant cell walls.\[2\] Blocking melanin synthesis by mutation or inhibitors prevents penetration because the melanin layer is essential for lowering the porosity of the appressorial wall. The turgor pressure in melanized appressoria is as high as 80 bars by accumulation of a high concentration of glycerol.\[2\] Pressure generated by turgor is exerted over the restricted area of the appressorial pore where the penetration peg emerges, resulting in penetration of plant tissue. Other fungi, including Colletotrichum species, also develop turgor pressures in appressoria as part of the penetration forces.\[4\] Forces produced by the cytoskeleton in penetration pegs may also contribute to appressorial penetration, particularly in fungi with low appressorium turgor pressures. A high concentration of cytoskeleton element in penetration peg may also be necessary to compensate for the difference in osmotic pressure between appressorial and host cell protoplasts.

Many fungal pathogens produce degradative enzymes, such as cutinases, laccases, polygalacturonases, and cellulases. For fungi that directly penetrate plant tissue without producing specialized infection structures, it is likely that cell wall-degrading enzymes play important roles in penetration. Some fungi are able to erode the plant cuticle, and localized degradation of plant cell wall materials has been observed along the penetration peg in several fungi. Even in fungi with high appressorium turgor, cell wall-degrading enzymes may be involved in penetration by modifying or softening the plant surface or cell wall. However, determining the importance of individual cell wall-degrading enzymes in plant penetration is complicated by the genetic redundancy and variable regulation of these enzymes.

INFECTIONOUS GROWTH

After penetration of host epidermal cells, infectious hyphae are differentiated from the bulbous primary vesicle. Infectious hyphae are often morphologically distinct from somatic hyphae or germ tubes. In some fungi, infectious hyphae may grow only between the cuticle and cell wall or within epidermal cell walls. Some endophytic fungi can grow extensively in plant tissues without damaging host cells and only cause disease symptoms when host plants are under certain stresses or developmental processes. In biotrophic pathogens, an elaborate structure known as the haustorium is formed within the penetrated cell for nutrient absorption. Most asexual fungi, however, do not produce haustoria. In necrotrophic pathogens such as Alternaria and Rhizoctonia species, plant cells are killed in advance of the invading hyphae, and the infectious hyphae grow between and into dead and dying cells. Some asexual pathogens are hemibiotrophic. During the initial biotrophic stage, the infectious hyphae can grow without killing plant cells. Switching from the biotrophic to necrotrophic phase occurs in the later stages and results in plant cell death. A few genes that are specifically expressed in the biotrophic phase or involved in the transition from biotrophic to necrotrophic phase have been reported in several Colletotrichum species.

During growth within the plant, the infectious hyphae must adapt to the plant environment and produce necessary enzymes for nutrient absorption. Infectious hyphae must also use different strategies to overcome constitutive and induced plant defenses, including degradation of preformed or induced antimicrobial compounds (such as pisatin demethylases or saponin-detoxifying enzymes and enzymes for scavenging reactive oxygen species). Some fungal pathogens produce molecules that suppress induced plant defenses.\[5\] For some pathogens with narrow host ranges, the fungal-plant interaction is governed by specific interactions between fungal avirulence and plant resistance genes. Fungal avirulence genes have been identified from several pathogens. These avirulence genes encode proteins with diverse biological functions and do not share common structural features.

Various fungi produce toxins or elicitors to damage plant cells. While some phytotoxins, such as trichotheccenes, interfere with general host cellular functions, some toxins are known as host-specific toxins, such as AAL- and HC-toxins produced by A. alternata and HC-toxin produced by Cochliobolus carbonum. Host-specific toxins are primary determinants of host range and can elicit...
disease symptoms with the same specificity as the pathogens. In pathogens causing vascular wilt diseases, such as *Fusarium oxysporum* and *Verticillium* species, the xylem vessels of infected stems and roots may be clogged with hyphae, spores, or polysaccharides produced by the pathogens. Cell wall–degrading enzymes, proteinases, and other enzymes also play important roles during infectious hyphal growth. For example, *B. cinerea* mutants disrupted in the endopolygalacturonase gene BCPG1 are significantly reduced in virulence, and transgenic tomatoes expressing a high level of polygalacturonase inhibitory proteins exhibit increased resistance to *B. cinerea*. [6]

**CONCLUSION**

In the past few years, both forward and reverse genetics approaches have been used to characterize genes important for plant infection processes and signal transduction pathways regulating infection-related morphogenesis. [7] However, our knowledge about molecular mechanisms involved in the intimate fungal-plant interactions is still very limited, particularly the events after penetration. [8] Recent advances in imaging techniques and genomics studies will be very helpful to further characterize fungal infection structures and efficiently identify genes critical for fungal pathogenesis (Fig. 1).

Mechanisms of Infection: Oomycetes

Paul R. J. Birch
David E. L. Cooke
Scottish Crop Research Institute, Dundee, U.K.

INTRODUCTION

Oomycetes are a diverse group of organisms that morphologically resemble fungi yet are members of the chromista, more closely related to key organisms in aquatic environments such as brown algae (e.g., kelp), golden-brown algae, and diatoms. The oomycetes include a tremendous range of free-living water molds, as well as saprophytes and pathogens of plants, algae, insects, fish, crustaceans, vertebrate animals, and microbes, including fungi. Plant pathogenic oomycetes cause devastating diseases of crop, ornamental, and native species and are arguably the most important pathogens of dicot plants. This article focuses on the most damaging groups, comprising more than 60 species of Phytophthora, several downy mildew genera (the most important being Peronospora, Plasmopora, and Bremia) and more than 100 Pythium species.

There is considerable diversity in oomycete infection strategies, from opportunistic or weakly pathogenic necrotrophs with wide host ranges, typified by many soil-borne Pythium species, through to the highly specialized, biotrophic, aerially disseminated, foliar Peronospora species. The genus Phytophthora spans these two extremes, including species colonizing leaf-litter, others that are described as “root-pruning,” and a range of highly specialized pathogenic hemibiotrophs. A common feature, however, is the absolute dependence on living plant tissue to complete their life cycle. Such diversity of pathogenic strategies begs the question of whether similar variation is manifest in infection mechanisms.

Oomycetes undergo many developmental stages throughout a successful infection cycle, including formation of sporangia, release of motile zoospores, their encystment and germination to form hyphae and appressoria, production of primary and secondary infection hyphae, haustoria, and finally sporangiophores. These stages facilitate dispersal, host recognition, adhesion, penetration, and colonization, encompassing biotrophic and/or necrotrophic phases of infection, finally returning to dispersal. In Fig. 1 we present a diagrammatic representation of “typical” oomycote infection structures and mechanisms and discuss the extent to which variation is apparent, using specific examples selected from key genera.

DISPERSAL AND RECOGNITION: SPORANGIA AND ZOOSPORES

Asexual, multinucleate sporangia develop from simple or compound sporangiophores at the apices of hyphae and are the most rapid means of reproduction (Fig. 1). The sporangia of airborne oomycetes, such as the potato late-blight pathogen Phytophthora infestans, are, in general, caducous, i.e., released freely from aerial hyphae and dispersed by wind or insects. In oomycetes predominantly colonizing roots or stem bases, sporangia are not freely released (noncaducous) and zoospores provide the main means of dispersal (Fig. 1). Generally, Pythium spp. produce noncaducous sporangia and downy mildews produce caducous sporangia. Within the Phytophthoras there are groups of species that span both extremes.

Sporangia may germinate directly to form an infection hypha or differentiate, through specialized cleavage vesicles, into between 10 and 30 zoospores that are released. The mechanism adopted varies, with zoospore production prevalent in Pythium species, through to an inability to form zoospores in Peronospora species. All Phytophthora species form zoospores but direct germination also occurs. The lack of the aquatic zoospore stage in Peronospora may reflect a greater adaptation to a terrestrial habitat, and sporangia thus provide the means of dispersal, recognition, and penetration of the host.

Zoospores are ephemeral, motile, biflagellate cells lacking cell walls and are often the initial agents of contact with the host. Under certain conditions they remain motile for several hours, although the distances traveled rarely exceed a few centimeters; passive movement in mass flow or surface water is a more significant means of dispersal. They can differentiate to form adhesive cysts, involving detachment or resorption of flagella, formation of a cell wall, and secretion of adhesive materials. Phytophthora cinnamomi cysts can differentiate into a sporangium that releases a single, secondary zoospore. This process can be repeated several times to increase the distance traveled to colonize a new host.

Zoospores respond to both plant exudates (chemotaxis) and to changes in electric currents (electrotaxis), although the pathological significance is unclear, since they are
Fig. 1 Typical oomycete infection cycle in host leaf (upper circle) or root (lower circle) tissues. In each circle, 1 represents mechanisms of dispersal of oomycetes, including wind or insect dispersal (upper circle) of sporangia (sp.), and attraction of zoospores (z) by electrotaxis or chemotaxis (lower circle); 2 direct germination of sporangia, or encystment (c) and germination of zoospores to penetrate the host along anticlinal epidermal cell walls (lower circle), via stomata, or through the periclinal cell wall with the aid of an appressorium (a) and infection hypha (ih) (upper circle); 3 hyphal colonization of host tissues and the development of intracellular haustoria (h); 4 sporulation on the leaf or root surface to complete and reinitiate the infection cycle. (View this art in color at www.dekker.com.)
attracted nonspecifically to roots of host and nonhost plants. However, many oomycetes with restricted host ranges respond to specific host-derived chemicals. For example, Phytophthora sojae zoospores are attracted to isoflavones in soybean seeds and root exudates.\[6\] Recently, van West et al.\[6\] demonstrated that Pythium aphanidermatum and Phytophthora palmivora differed in their responses to electric currents. P. palmivora is anodotactic and attracted to rye grass root tips, whereas Py. aphanidermatum is cathodactic and attracted to a region behind rye grass root tips and to wounds, which are cathodic.

**CYST GERMINATION, APPRESSORIUM FORMATION, AND HOST PENETRATION**

During zoospore encystment and germination, adhesive materials are secreted that are important in preventing dislodgement of cysts and in providing attachment as physical force is exerted during host penetration. The adhesive materials are unknown, although genes encoding mucin-like proteins, termed Car, have been postulated to play a role in attachment and are up-regulated in germinating cysts and appressoria.\[7\] Moreover, a protein called CBEL, identified in Phytophthora parasitica, contains a fungal-like cellulose binding domain and is required for attachment to cellulose.\[8\]

Phytophthora cysts germinate 20 to 30 minutes after encystment, and hyphae directly penetrate host roots either intercellularly along anticlinal cell walls, or intracellularly through the periclinal wall of epidermal cells.\[9\] Both forms of penetration are also observed in the Pythium spp. Aerial plant parts are similarly infected by Phytophthorae and downy mildews but with an additional means of direct entry via stomata.

Both root- and leaf-infecting oomycetes can form appressorium-like structures, hyphal swellings that are manifest prior to penetration of host epidermal cells. In contrast to those formed in fungal plant pathogens such as Magnaporthe grisea, oomycete appressorium-like structures lack cross-walls separating them from the spore and germ tube. However, there is little doubt that they are involved in host penetration and thus meet one of the important criteria that define appressoria.\[9\]

Appressorium-like structures are formed with greater prevalence in oomycetes invading foliar host tissues. Nevertheless, whether in leaf- or root-infecting species, they are more frequently formed when directly penetrating the periclinal wall of epidermal cells, possibly due to the greater demands of overcoming more challenging host cell wall barriers.\[9\]

Penetration of host cell walls involves not only exertion of physical pressure but also production of enzymes facilitating breakdown of cell wall polymers, including pectin and cellulose. Various extracellular hydrolytic enzymes, including cellulase, \(\beta\)-glucosidases and 1,3-\(\beta\)-glucanases were purified from P. infestans culture filtrates\[10\] and genes encoding some of these, and also cutinases and polygalacturonases, have been identified in a range of oomycetes.\[11\]

**HOST COLONIZATION AND HAUSTORIUM FORMATION**

The infection tube that develops from a P. infestans appressorium-like structure penetrates a leaf epidermal cell to form a dilated hyphal structure termed a ‘‘primary hypha’’ or ‘‘infection vesicle.’’ This ‘‘biotrophic’’ structure is surrounded by the host plasma membrane. One or more secondary hyphae develop that traverse the cell and exit, either penetrating a mesophyll cell or entering intercellular spaces. The hyphae ramify through intercellular spaces, where they form a further ‘‘biotrophic’’ structure within living plant cells, the haustorium (Fig. 1).\[12\] Unlike the spherical bodies typical of many true-fungi, those in Phytophthora spp., downy mildews, and Pythium spp. are fingerlike. As with the infection vesicle, they are surrounded by the host plasma membrane and make no direct contact with host cytoplasm. Their outer cell wall comprises an extrahaustorial matrix, an electron dense substance of unknown function laid down at the initial stage of haustorial penetration of the host cell wall.\[9,12\] Interestingly, haustoria of Phytophthora spp. are reported to lack nuclei\[9,12\] whereas those in downy mildews may be uninucleate or multinucleate.\[13\]

Haustoria are biotrophic, since they are formed within living plant cells and are presumably involved, at least in part, in exchange of nutrients from the host to the pathogen. Subtle penetration of living host cells implies avoidance or suppression of host defences. Doke et al.\[14\] proposed the production of a glucan by P. infestans that suppresses the hypersensitive response, a form of programmed cell death or host cell suicide to which haustoria would be particularly vulnerable. Furthermore, a family of glucanase inhibitor proteins (GIPS) in P. sojae inhibit host endo-\(\beta\)-1,3-glucanases.\[15\] GIP inhibition not only prevents host glucanases from directly attacking pathogen cell walls but also prevents their activity leading to release of elicitor-active oligosaccharides that induce additional host defenses.

In susceptible hosts, oomycetes acquire sufficient nutrients to ramify through plant tissues and sporulate on the root, stem, or leaf surface, releasing sporangia...
and/or zoospores to complete and reinitiate the cycle of infection.

FUTURE PROSPECTS

The cytology of plant infection by oomycetes has been extensively studied over many years. Infection follows a cycle of clearly defined developmental stages. With each cell type that is formed, countless genes will be up- or down-regulated, not only to drive cellular development but also to facilitate host invasion and counteract host defences. The molecular bases of pathogenicity are poorly understood, although the current era of genomic research promises to accelerate our understanding of molecular processes in two key, model oomycetes, *P. sojae* and *P. infestans*.[5,11]

Mechanisms of Infection: Rusts

Matthias Hahn
University of Kaiserslautern, Kaiserslautern, Germany

INTRODUCTION

Among the various infection strategies used by plant pathogenic fungi, growth in living host tissue (biotrophy) and formation of haustoria are hallmarks of rust fungi. Rust infection is also unique in the ability of a germ hypha to sense surface topography in order to achieve invasion via stomata. Our understanding of biotrophic parasitism and the crucial role of rust haustoria in the uptake of sugars and amino acids from infected host cells has increased significantly using molecular and cytological methods. This article summarizes our knowledge about host invasion and establishment of rust infection.

BIOLOGY AND INFECTION MECHANISMS OF RUST FUNGI

With more than 5000 described species, rust fungi (Uredinales, Basidiomycetes) form a major group of plant pathogens. Named after their noticeable sori, which are often filled with reddish-brown (or yellow, black, etc.) colored spores, rust fungi have destroyed cereal crops since ancient times, and still cause significant damage to a large variety of economically important plants (e.g., legumes, coffee, pines). The most conspicuous property of rust fungi is their highly complex life cycle and their ability to switch hosts. Macrocytic rust species produce up to five different spore forms, but reduced life cycles also exist. Three types of rust spores are infectious, namely uredo- and aecidiospores (dikaryotic) and basidiospores (monokaryotic, haploid). In heteroecious rusts, which need two different host plants to complete their life cycle, dikaryotic spores infect one species and monokaryotic spores infect another. A well-known example is *Puccinia graminis*, which infects wheat as a dikaryon and barberry as a monokaryon. Infection by uredo- and aecidiospores usually occurs via stomata and involves a series of infection structures (see below). In contrast, basidiospores penetrate epidermal cells directly, giving rise to a mycelium which shows a lower degree of cellular differentiation and which often tends to grow toward vascular host tissue.\(^1\)

SPORE ATTACHMENT, GERMINATION, AND INFECTION STRUCTURE FORMATION

Rust uredospores are spread by air, sometimes over very long distances, to reach their host plants. They have hydrophobic coats, which allow adhesion to aerial hydrophobic plant surfaces. Irreversible attachment, however, requires the release of adhesive gel-like material consisting of carbohydrates and glycoproteins. It accumulates—in the presence of water, by passive hydration and swelling—between spore and host surface. Hydrolytic enzymes such as esterases and cutinases increase the adhesive properties of the secreted material, possibly by ‘‘eroding’’ the hydrophobic cuticular layer and converting it to a hydrophilic one.\(^2\) Subsequently, the germ tube emerges and grows over the plant surface, with the tip of the hypha being closely attached to the cuticle. Localization of stomata as entry points for subsequent invasion is achieved by a unique surface-sensing mechanism of the germinated rust uredospore. Growth direction of the germ tube is aligned perpendicular to repetitive features formed by the ridges or grooves of adjacent epidermal cell walls. This increases the chance that the fungus will hit a stoma. Subsequently, when the germ tube tip reaches a stomatal guard cell, a new type of hypha called an appressorium is formed. Allowing rust germings to develop on artificial surfaces with ridges or grooves of defined dimensions proved that topographical features provide the key signals for this differentiation process. For instance, a ridge of approximately 0.5 \(\mu\)m height was most effective in the case of the bean rust *Uromyces appendiculatus*, and this height is similar to the height of the guard cell lip of bean leaves.\(^3\) Within a few minutes after topographical recognition, germ tube elongation is stopped and appressorium formation is initiated. There is evidence that ion fluxes across the plasma membrane in the tip region of the germ tube, followed by cytoskeletal rearrangements, are involved in transducing the mechanical signal ‘‘presence of the stoma’’ into the response ‘‘appressorium formation and invasion.’’ Invasion of host tissue occurs by means of additional infection structures, i.e., penetration hypha, infection hypha, and haustorial mother cell (Fig. 1). In several rust species, these structures are formed without additional signals. The
formation of infection structures in response to artificial signals has made it possible to study molecular events associated with the early invasion process of rust fungi in the absence of a host plant.

During invasion, rust fungi secrete low amounts of host cell wall degrading enzymes, which is strictly dependent on infection structure formation. For instance, the secretion of several isoforms of cellulases and pectin esterases was not observed until appressorium formation and occurred in a sequential fashion. Another enzyme, pectate lyase, was not produced until haustorium mother cell differentiation. In contrast to the situation in many other fungi, production of these enzymes was not subject to glucose repression, and no substrate induction was observed except for pectate lyase, which was secreted only in the presence of pectate (=polygalacturonate).[4]

Although it has not been proven, it is plausible that the abovementioned enzymes—together with others—aid in the attachment of the invading hyphae to cells walls of the host and in the subsequent penetration of the walls during haustorium formation. The highly controlled secretion of these lytic enzymes could be important in minimizing damage to the host cell that is invaded during haustorium formation.

**HAUSTORIA**

In contrast to the infection structures mentioned above, haustoria are formed only within living host cells. This makes their experimental analysis difficult, even more so since rusts are obligate biotrophs which cannot be cultivated (with few exceptions) in artificial media. Therefore, it is not possible to apply powerful molecular genetic experimental tools such as genetic transformation and knockout mutagenesis to rust fungi.

Haustoria certainly play a crucial role for the establishment of biotrophic rust infections. They are part of a parasitic mycelium which grows largely intercellularly. While being formed within host cells, they remain surrounded by a modified plasma membrane. By this means, a highly specialized interface is formed. Extensive cytological studies using light and electron microscopy identified the unique structural properties of haustoria that are likely to be correlated with their function. According to our present view, rust haustoria are centrally involved 1) in biotrophic nutrient acquisition; 2) in vitamin biosynthesis; and 3) in maintaining the biotrophic relationship with the host plant. Whereas only little experimental evidence is available about the last

---

**Fig. 1** Infection by rust fungi (*Uromyces* spp.). A germ tube (GT) emerges from an uredospore (S) attached to the leaf surface by an adhesion pad (P). Above the stoma, an appressorium (A) is formed, a penetration hypha (PE) grows into the substomatal chamber, and an infection hypha (IH) extends into the apoplastic space. A haustorial mother cell (HM) attaches to the host cell wall and penetrates into the cell, giving rise to a haustorium (H). Unique features of the haustorium are the neckband (NB) and the interfacial, extrahaustorial matrix (yellow) surrounded by the host-derived extrahaustorial membrane (EHM). After formation of the primary haustorium, the infection hypha forms branches and the biotrophic mycelium proliferates within the leaf tissue. (From Ref. 6.) (View this art in color at www.dekker.com.)
According to the diagram shown in Fig. 2, nutrients released from the infected host cell into the interface (extrahaustorial matrix) diffuse across the interface layer and the haustorial wall to the haustorial membrane, where they are transported by proton symport carriers into the haustorial cytoplasm. The driving force for metabolite uptake is a proton gradient across the haustorial plasma membrane generated by the activity of a plasma membrane H⁺-ATPase. This model is supported by the following experimental evidence: Genes encoding amino acid and hexose carriers have been cloned from a rust fungus and were found to be transcribed at high levels in haustoria, but not (or only at low levels) in early infection structures and the intercellular hyphae. With immunolocalization, a proton-coupled hexose carrier was detected exclusively in the haustorial plasma membrane, convincingly showing that this is the major site of sugar uptake into the fungus (Fig. 3). Furthermore, the activity of the rust plasma membrane H⁺-ATPase was shown to be highest in a membrane preparation isolated from rust haustoria, so this enzyme could well be responsible for the generation of the membrane potential required for secondary active nutrient uptake.

Evidence for major metabolic activities in haustoria also came from the identification of two highly expressed genes that encode enzymes required for thiamine biosynthesis. One of these enzymes was detected in

---

**Fig. 2** Model for uptake of nutrients by a rust haustorium from an infected plant cell. The proton-pumping activity of a plasma membrane H⁺-ATPase in the haustorial plasma membrane generates a proton gradient and membrane potential. They are used by proton-coupled carrier proteins that transport hexose sugars (glucose, fructose) and amino acids into the haustorium. One hexose transporter and three amino acid transporters are known in the broad bean rust. (View this art in color at www.dekker.com.)

**Fig. 3** Immunolocalization of a hexose transporter within the plasma membrane of rust haustoria. A resin-embedded section of a rust-infected broad bean leaf was incubated first with an antibody against a rust hexose transporter, followed by a fluorescence-labeled secondary antibody. Labeling is visible only in the periphery of rust haustoria (H). V, plant vacuole; C, chloroplast; A, apoplast. (From Ref. 6.) (View this art in color at www.dekker.com.)
haustoria in high concentrations, but only at low levels in other parts of the rust mycelium. Thus, haustoria appear to be not only the principal sites of nutrient uptake, but also of the biosynthesis of vitamin B1 and possibly other important metabolites that are not provided by the host plant.\[6\]

CONCLUSION

The biotrophic lifestyle provides rust fungi with a continuous supply of nutrients and allows them to escape competition with most other herbivorous microorganisms. To achieve this goal, rust fungi need to suppress host cell death, which is usually associated with the most powerful plant defense mechanism—the hypersensitive response. How defense suppression is accomplished remains unknown, but there is evidence that haustoria also play a crucial role in this process.

INTRODUCTION

The daily average income of nearly one billion people is less than one U.S. dollar. Globally, about 170 million people are infected with hepatitis C virus, with 3–4 million new infections each year. WHO Department of Communicable Disease Surveillance and Response reports that more than one third of world population is infected with hepatitis B. In Asia, the prevalence of chronic hepatitis B and C is very high (about 110 million infected by HCV and 150 million infected by HBV). A large majority of hepatitis C–infected patients have severe liver cirrhosis and currently there is no vaccine available for this disease. The annual requirement of human, insulinlike growth factor 1 (IGF-1) per cirrhotic patient is 600 mg (1.5–2 mg per day) and the cost of IGF-1 per mg is $30,000. Current annual cost of interferon therapy for viral hepatitis is $26,000 per year. Therefore, agricultural scale production of therapeutic proteins and vaccines is necessary to meet such large demand at a reasonable cost. Recent observation of the potential ability of one acre of transgenic tobacco plants to produce 600 million anthrax vaccines makes this a promising new approach.

CHLOROPLAST-DERIVED THERAPEUTIC PROTEINS

Chloroplast-derived biopharmaceuticals should be inexpensive to produce and store, easy to scale up for mass production, and free of animal or human pathogens. Chloroplast genetic engineering is an environmentally friendly approach and offers biological containment of transgenes. Expression of thousands of copies of transgenes per plant cell via chloroplast genomes has yielded the highest level of foreign proteins ever reported in transgenic plants. Chloroplast transgene expression is also free of position effect and gene silencing, frequently encountered in nuclear transgenic plants that result in low levels of expression. Oral delivery of pharmaceuticals should eliminate the purification steps that usually account for most of production costs. Edible vaccines may be the only practical solution to combat bioterrorism agents. The successful engineering of tomato chromoplasts for high-level transgene expression in fruits, coupled with hyper expression of vaccine antigens and the use of plant-derived, antibiotic-free selectable markers, augurs well for oral delivery of edible vaccines or biopharmaceuticals that are currently beyond the reach of those who need them most. However, because of the concerns of dosage and potential for contamination with the food supply, plant derived pharmaceuticals should be prescribed as a freeze-dried powder (with appropriately identified dosage) and fully contained.

PLANT-DERIVED BIOPHARMACEUTICALS AND HUMAN PROTEINS

Generally, levels of pharmaceutical proteins expressed in nuclear transgenic plants have been less than the levels needed for commercial feasibility, if the protein must be purified. Recombinant hepatitis B surface antigen (HBsAg) expressed via the nuclear genome induced only a low-level serum antibody response in a small human study, probably reflecting the low level of expression (1–5 ng/g fresh weight) in transgenic lettuce. Recent studies increased the level of expression up to 8.35 μg/g fresh tuber (0.000835% fresh weight). Despite such low levels of expression, adequate primary antibody response was observed in animals fed with uncooked potato tubers, but this response was lost when tubers were cooked. Similarly, Norwalk virus capsid protein expressed in potatoes caused oral immunization when fed to mice, but expression levels were too low for large-scale oral administration. Similar to viral proteins, expression of genes encoding several human proteins in transgenic plants has been disappointingly low, e.g., human serum albumin, 0.02%; human protein C, 0.001%; human epidermal growth factor, 0.001% and erythropoietin,
0.0026% of total soluble protein; human interferon-β was 0.000017% of fresh weight.[8–10] Therefore, there is a great need to increase expression levels of human, viral, or bacterial proteins or antigens in order to enable commercial production of pharmacologically important proteins in plants.

**CHLOROPLAST TRANSGENIC SYSTEM**

Chloroplast genetic engineering was conceived as a novel approach to increase expression levels and overcome problems of nuclear genetic engineering.[11–13] Foreign genes have been integrated into the chloroplast genome of several crop plants, including tobacco, tomato, and potato (up to 10,000 copies of transgenes per cell), resulting in accumulation of recombinant proteins several hundred-fold higher than nuclear transgenic plants (up to 47% of the total soluble protein).[14] Targeted integration of transgenes at specific sites into the chloroplast genomes eliminates the “position effect” frequently observed in nuclear transgenic plants resulting from random integration of transgenes.[1,2] In addition, gene silencing has not been observed in transgenic chloroplasts, in spite of extraordinarily high levels of transgene expression, whereas it is a common phenomenon in nuclear transformation.[2] Because of these reasons, expression and accumulation of foreign proteins is uniform in independent chloroplast transgenic lines.[5] It has been shown that multiple genes can be engineered in a single transformation event via the chloroplast genome, regulated by a single promoter; this facilitates coordinated expression of multisubunit proteins or multicomponent vaccines, or engineering new pathways. This was demonstrated by successful expression and assembly of monoclonal antibodies[15] or multigene bacterial operons[14] in transgenic chloroplasts. Yet another advantage is the lack of toxicity of foreign proteins to plant cells when they are compartmentalized within chloroplasts.[5,16] Chloroplast genetic engineering is an environmentally friendly approach, minimizing several environmental concerns, including transgene containment.[3] Most importantly, chloroplasts are able to process eukaryotic proteins, including correct folding and formation of disulfide bridges. Accumulation of large quantities of a fully assembled form of human somatotropin with the correct disulfide bonds provides strong evidence for hyperexpression and assembly of pharmaceutical proteins using this approach.[17] In addition, functional assays showed that chloroplast-synthesized cholera toxin β subunit (CTB) binds to the intestinal membrane GM1-ganglioside receptor, confirming correct folding and disulfide bond formation of the plant-derived CTB pentamers.[5] Such folding and assembly of foreign proteins should eliminate the need for highly expensive in vitro processing of pharmaceutical proteins produced in recombinant organisms. For example, 60% of the total operating cost for the commercial production of human insulin in *Escherichia coli* is associated with in vitro processing (formation of disulfide bridges and cleavage of methionine).[18]

**Expression of Human Serum Albumin in Transgenic Chloroplasts**

Human serum albumin (HSA) accounts for 60% of the total protein in blood serum and it is the most widely used intravenous protein. Currently, HSA is produced primarily by the fractionation of blood serum. Because of unique advantages of the chloroplast genetic engineering approach, HSA was expressed in transgenic chloroplasts[19,20] Regulation of HSA under the control of a Shine-Dalgarno sequence (SD), 5’ *psbA* region, or the cry2Aa2 untranslated region (UTR) resulted in different levels of expression in transgenic chloroplasts from seedlings: 0.8, 1.6, and 5.9% of HSA in total protein (tp), respectively. On the other hand, a maximum of 0.02, 0.8, and 7.2% of HSA in tp was observed in transgenic potted plants regulated by SD, cry2Aa2 UTR, or 5’ *psbA* region, respectively, demonstrating excessive

---

**Fig. 1** Electron micrograph of immunogold labeled inclusion bodies of human serum albumin (HSA) in transgenic chloroplasts (magnification × 6300). HSA is the most widely used intravenous protein in human therapies.
proteolytic degradation, unless compensated by enhanced translation. The psbA-HSA expression was subject to developmental and light regulations, with the lowest expression observed in seedlings and maximal expression (11.1% tsp) under continuous illumination. This is the highest expression of HSA so far and five hundred–fold higher than previous reports of HSA expression in leaves of nuclear transgenic plants. Accumulation of HSA was so high that inclusion bodies were observed within transgenic chloroplasts (Fig. 1). Formation of HSA inclusion bodies not only offered protection from proteolytic degradation but also provided a simple method of purification from other cellular proteins by centrifugation. HSA inclusion bodies could be readily solubilized to obtain monomeric form using appropriate reagents. The cry2Aa2 UTR–mediated expression in seedlings and chromoplasts, although as efficient as 5′ psbA region, is independent of light regulation and should therefore facilitate expression of foreign genes in nongreen tissues, thereby enabling oral delivery of pharmaceuticals. The regulatory elements used in this study should serve as a model system for enhancing expression of foreign proteins that are highly susceptible to proteolytic degradation and provide advantages in purification.

**Optimization of Codon Composition and Regulatory Elements for Expression of Human Insulinlike Growth Factor 1 in Transgenic Chloroplasts**

Human insulinlike growth factor 1 (IGF-1) is a potent multifunctional anabolic hormone produced by the liver. IGF-1 polypeptide is composed of 70 amino acids with a molecular weight of 7.6 kDa and contains three disulfide bonds. IGF-1 is involved in the regulation of cell proliferation and differentiation of a wide variety of cell and tissue types, and plays an important role in tissue renewal and repair. One cirrhotic patient requires 600 mg of IGF-1 per year and the cost of IGF-1 per mg is $30,000.[21] In the past, IGF-1 has been expressed in E. coli but the protein cannot be produced in the mature form, because E. coli does not form disulfide bonds in the cytoplasm. In order to increase the expression levels, a synthetic IGF-1 gene with chloroplast optimized codons was made. The integration of the IGF-1 gene into the tobacco chloroplast genome was confirmed using Polymerase chain reaction (PCR) and Southern analyses. The IGF-1 protein was detected in large quantities in transgenic chloroplasts by western blot analysis. The ELISA performed on the transgenic lines showed expression levels up to 32% IGF-1 of the total soluble protein, both in the native and synthetic genes. This is the highest level of pharmaceutical protein reported in transgenic plants.[19,22] Most importantly, these observations show that the chloroplast translation machinery is quite flexible, unlike the bacterial translation machinery that translated only the synthetic chloroplast codon–optimized IGF-1 gene.

**Expression and Functionality of Human Interferon in Transgenic Chloroplasts**

Interferon alphas (IFNαs) are known inhibitors of viral replication and cell proliferation. In addition, they are potent enhancers of the immune response and have many uses in the clinical treatment. A specific subtype, IFNα2b, was first approved in 1986 for the treatment of hairy cell leukemia by the Food and Drug Administration and has shown efficacy in a growing number of treatments for various viral and malignant diseases. However, the recombinant IFNα2b now on the market is being produced through an E. coli expression system and due to necessary in vitro processing and purification, the average cost of treatment is $26,000 per year. Recently, recombinant IFNα2b is used to treat patients suffering from West Nile virus. The 2 week treatment costs $2500 per patient. This drug is usually administered by injection, but the development of severe side effects is quite common. Also, up to 20% of patients produce anti-IFNα antibodies when the IFNα2b aggregates with human serum albumin in the blood. These antibodies are an undesirable response and lessen the effectiveness of the treatment. Evidence links the negative side effects to route of administration and dosage parameters. In fact, oral administration of natural human IFNα has proven to be therapeutically useful in the treatment of various infectious diseases.

Oral delivery of IFNα2b expressed via the chloroplast genome may eliminate some of these problems. Therefore, a recombinant IFNα2b containing a polyhistidine purification tag and a thrombin cleavage site was generated and integrated into the chloroplast genome of petit Havana and into a low nicotine variety of tobacco, LAMD-609.[15,19,23] Chloroplasts correctly process and fold human proteins as well as form the requisite disulfide bonds. In addition, bioencapsulation in plants cells can protect recombinant proteins from degradation in the mammalian gastrointestinal tract, and plant-based production systems are free of human pathogens. Western blots detected monomers and multimers of IFNα2b in both tobacco varieties using interferon alpha monoclonal antibody (MAB). Southern blots confirmed stable, site-specific integration of transgenes into chloroplast genomes and determined homoplasmy or heteroplasmy in the T0 generation. In the petit Havana transgenic lines, homoplasmy of chloroplast genomes occurs in the first generation, and this corresponds to the highest level of IFNα2b expression. ELISAs were used to quantify up to 18.8% of total soluble protein in petit Havana and up to
12.5% in LAMD-609. IFNα2b functionality was determined by the ability of IFNα2b to protect HeLa cells against the cytopathic effect of encephalomyocarditis virus (EMC) and RT PCR. Chloroplast derived IFNα2b was as active as commercially produced Intron A. The mRNA levels of two genes induced by IFNα2b: 2'-5' oligoadenylate synthase and STAT-2, were tested by RT-PCR using primers specific for each gene. Chloroplast derived IFNα2b induced expression of both genes similar to commercial IFNα2b. These expression levels and functionality are ideal for purification and further use in oral IFNα2b delivery or preclinical studies.

Expression of Bacillus anthracis Protective Antigen in Transgenic Chloroplasts for an Improved Vaccine Against Anthrax

Bacillus anthracis is the causative agent for the anthrax disease, which has become a serious threat due to its potential use in bioterrorism and recent outbreaks among wild-life in the United States. CDC lists B. anthracis as a category A agent and estimates the cost of an anthrax attack to exceed $26 billion per 100,000 exposed individuals. Concerns regarding vaccine purity, the current requirement for six injections followed by yearly boosters, and a limited supply of the key protective antigen (PA), underscore the urgent need for an improved vaccine. Therefore, the gene coding for PA (pag) was cloned into a chloroplast vector along with a regulatory signals to enhance translation. Chloroplast integration of the transgenes was confirmed by PCR and Southern blot analyses. Crude plant extracts contained up to 2500 μg PA/g of fresh leaf tissue. Exceptional stability of full length PA in leaves stored for several months or in crude extracts was observed, even in the absence of protease inhibitors. PA expression was light-regulated, and maximal expression was observed under continuous illumination. Co-expression of the ORF 2 chaperonin from Bacillus thuringiensis did not increase PA accumulation or fold it into cuboidal crystals in transgenic chloroplasts. Both trypsin and chymotrypsin proteolytic cleavage sites present in PA were protected in transgenic chloroplasts. Furin or furinlike proteases are absent in chloroplasts because only PA 83 was observed. Both CHAPS and SDS detergents extracted PA with equal efficiency and PA was observed in the soluble fraction. Chloroplast-derived PA efficiently bound to anthrax toxin receptor, underwent proper cleavage, heptamerized, and bound lethal factor, resulting in macrophage lysis; up to 25 μg functional PA per ml crude extract was observed. With anticipated expression level up to 6.24 kg PA per acre (three cuttings), assuming 50% loss of PA during purification from plant extracts and at 5 μg PA per dose (the current vaccine contains 1.75–7 μg/ml PA), 600 million doses of vaccine (free of contaminants) could be produced per acre of transgenic tobacco. This opens a new approach to combat bioterrorism.

Expression of Monoclonals in Transgenic Chloroplasts

Owing to their remarkable specificity and therapeutic nature for defined targets, monoclonal antibodies are emerging as therapeutic drugs at a fast rate. The chloroplast genome was chosen for transformation with antibody genes due to tremendously high levels of foreign protein expression, the ability to fold, process, and assemble foreign proteins with disulfide bridges, and simpler purification and transgene containment via maternal inheritance. To enhance translation, a codon-optimized gene under the control of specific 5' untranslated regions (UTRs) was used. IgA-G, a humanized, chimeric monoclonal antibody (Guy’s 13) has been successfully synthesized and assembled in transgenic tobacco chloroplasts with disulfide bridges. Guy’s 13 recognizes the surface antigen Streptococcus mutans, the bacteria that causes dental cavities. In this study, integration into the chloroplast genome was confirmed by PCR and southern blot analyses. Western blot analysis revealed the expression of heavy and light chains individually, as well as the fully assembled antibody, thereby suggesting the presence of chaperonins for proper protein folding and enzymes for formation of disulfide bonds within transgenic chloroplasts.

Expression of Anti-Microbial Peptides (AMP) to Combat Drug-Resistant Pathogens

There are several human pathogenic bacteria that are drug resistant or have acquired resistance over a period of time. There is an urgent need to explore alternate ways of combating such bacteria. Magainin and its analogues have been investigated as a broad spectrum topical agent, a systemic antibiotic, a wound-healing stimulant, and an anticancer agent. Magainin’s analogue MSI-99, a synthetic lytic peptide, has been recently expressed via the chloroplast genome. This AMP is an amphipathic alpha helix molecule and possesses affinity for negatively charged phospholipids found in the outer membrane of all bacteria. The probability of bacteria adapting to the lytic activity of this peptide is very low. It was observed that the lytic peptide is expressed at high levels, i.e., 21.5% of tsp. A multidrug-resistant gram negative bacteria, Pseudomonas aeruginosa, which is an opportunistic pathogen for plants, animals, and humans, was used for in vitro assays to test for the effectiveness of the lytic peptide expressed in the chloroplast. Cell extracts prepared from T1 generation plants resulted in 96% inhibition in growth.
of this pathogen. This result is highly encouraging in the exploration treatments against drug-resistant bacteria in general and to cystic fibrosis patients in particular because of their high susceptibility to P. aeruginosa.

Pharmaceutical companies are exploring the use of lytic peptides as broad-spectrum topical antibiotics and systemic antibiotics. It has been reported that the outer leaflet of melanoma and colon carcinoma cells express three- to seven fold more phosphatidylserine than their noncancerous counter parts. Previous studies have reported that analogues of magainin 2 were effective against hematopoietic, melanoma, sarcoma, and ovarian teratoma lines. Given the preference of this lytic peptide for negatively charged phospholipids, MSI-99 shows potential as an anticancer agent. The minimum inhibitory concentration of MSI-99 was investigated. Based on total inhibition of 1000 P. syringae cells, MSI-99 was most effective against P. syringae, requiring only 1 μg/1000 bacteria.[26] Because the lytic activity of antimicrobial peptides is concentration dependent, the amount of antimicrobial peptide required to kill bacteria was used to estimate the level of expression in transgenic plants. Based on the minimum inhibitory concentration, it was estimated that transgenic plants expressed MSI-99 at 21.5–43% of the total soluble protein.

**Oral Delivery of Recombinant Proteins via Cholera Toxin B Subunit (CTB)**

CTB has previously been expressed in nuclear transgenic plants at levels of 0.01 (leaves) to 0.3% (tubers) of the total soluble protein. To increase expression levels, the chloroplast genome was engineered to express the CTB gene.[5] Expression of oligomeric CTB at levels of 4–5% of total soluble plant protein was observed. PCR and Southern blot analyses confirmed stable integration of the CTB gene into the chloroplast genome. Western blot analysis showed that transgenic chloroplast–expressed CTB was antigenically identical to commercially available purified CTB antigen. Also, GM1-ganglioside binding assays confirm that chloroplast synthesized CTB binds to the intestinal membrane receptor of cholera toxin.[5] Transgenic tobacco plants were morphologically indistinguishable from untransformed plants and the introduced gene was found to be inherited stably in the subsequent generation as confirmed by PCR and Southern blot analyses. In addition to establishing unequivocally that chloroplasts are capable of forming disulfide bridges to assemble foreign proteins, the increased production of an efficient transmucosal carrier molecule and delivery system, such as CTB, in plant chloroplasts makes plant-based oral vaccines and fusion proteins with CTB needing oral administration a much more feasible approach. Spontaneously forming CTB pentamers have exhibited intact transcytosis to the external basolateral membrane of intestinal epithelium and have been widely used as oral vaccine vehicles. It is thus feasible to produce CTB fusion proteins for oral delivery.

**CONCLUSION**

The first pharmaceutical protein expressed in transgenic chloroplasts was a protein-based polymer with varied biomedical applications, including prevention of postsurgical adhesions/scars, use in wound coverings, artificial pericardia, tissue reconstruction, and programmed drug delivery.[27] Since then several biopharmaceutical proteins have been expressed in transgenic chloroplasts. Hyperexpression of several human blood proteins, including human serum albumin, Magainin, interferons, somatotropin and insulinlike growth factors in transgenic chloroplasts for mass production and purification, makes chloroplast genetic engineering an invaluable approach to realize the full potential of plant-derived biopharmaceuticals. The successful engineering of tomato chloroplasts for high-level transgene expression in fruits, coupled with hyperexpression of vaccine antigens (for anthrax, cholera, plague) and the use of plant-derived, antibiotic-free selectable markers, augurs well for the oral delivery of edible vaccines or biopharmaceuticals that are currently beyond the reach of those who need them most.

Meiosis

Wojciech P. Pawlowski
Lisa C. Harper
W. Zacheus Cande
University of California, Berkeley, California, U.S.A.

INTRODUCTION

Meiosis is the specialized pair of cell divisions that alter the genetic content of the nucleus from 2n (diploid) to 1n (haploid) and lead to the production of gametes. Following a premeiotic S phase, homologous chromosomes pair and synapses. This is followed by meiotic recombination and subsequent chiasmata formation between the paired homologous chromosomes. Chromosome pairing and the formation of chiasmata ensure the bipolar attachment of homologous chromosomes to the spindle, which is required for the reductional division of meiosis I that leads to the separation of homologs. This is followed by a modified cell cycle lacking an S phase. A second, equational division leads to the separation of sister chromatids and a halving of the chromosome number per cell. The general progression of meiosis is highly conserved, and is thus similar in yeast, humans, and plants.

PLANTS AS MODEL SYSTEMS FOR STUDYING MEIOSIS

The availability of large numbers of cells undergoing meiosis (meiocytes) in anthers has made plants excellent models for studying meiosis. Maize is one of the few organisms with a large genome where pairing and synapsis is amenable to analysis by a combination of cytological, genetic, and molecular techniques. The features of meiosis in *Arabidopsis*, at least at a cytological level, are conventional and comparable to those of other plants, but it has been the ease of gene discovery in this organism that has led to the adoption of *Arabidopsis* for meiosis research.

CHROMOSOME BEHAVIOR DURING MEIOTIC PROPHASE

The accurate segregation of chromosomes at the first division of meiosis requires that homologous chromosomes pair and recombine with each other to form bivalents (Fig. 1). The pairing and crossing over of homologous chromosomes occurs in the extensive prophase of meiosis. Dramatic changes in chromosome behavior and morphology during meiotic prophase have been used to subdivide the prophase into stages: leptotene, zygotene, pachytene, diplotene, and diakinesis.[1–3] In leptotene, the decondensed clouds of chromatin are organized into long, thin fibers by the assembly of a proteinaceous core—the axial element—onto the chromosomes. During zygotene, homologous chromosomes pair and begin to tightly associate, or synapse, along their length when the central element of the synaptonemal complex (SC) is installed between the homologous chromosomes. By pachytene, SC formation is complete and meiotic recombination between homologs is resolved. In diplotene, the synaptonemal complex disassembles and chiasmata, which are responsible for holding the homologous chromosomes together, are visible. Finally, in diakinesis, the chromosomes undergo a final stage of chromosome condensation just prior to metaphase.

TELOMERES CLUSTER ON THE NUCLEAR ENVELOPE AT THE BEGINNING OF MEIOTIC PROPHASE

Before chromosomes synapse during zygotene, the nucleus becomes highly polarized by the formation of the telomere bouquet (Fig. 1). The ends of the chromosomes become tightly clustered together on the inner surface of the nuclear envelope, resulting in a structure resembling a bouquet of flowers. The close relationship between the telomere clustering and chromosome pairing has led to the suggestion that the bouquet may help to facilitate pairing. By coaligning the ends of the chromosomes, homologous regions of the chromosomes are vectorially aligned and within the same region of the nucleus. In addition, the clustering of telomeres on the nuclear envelope may serve to restrict the homology search to a much smaller volume of the nucleus. Consistent with this potential role is the general observation that synopsis is typically initiated near the telomeres. Mutants defective in bouquet formation show delay in the progression of meiosis and severe defects in pairing and synopsis.[4]
**CHROMOSOME PAIRING AND SYNAPSIS**

In some organisms, such as the hexaploid wheat and *Drosophila*, the pairing of homologous chromosomes occurs prior to meiosis. However, in many other organisms such as maize, oat, humans, and mice, homologous chromosomes are not associated with each other until zygotene. Regardless of when chromosomes pair, a major question in meiosis is, how do the homologous chromosomes identify and associate with each other? The axial cores of the synaptonemal complex do not appear to contain the information for distinguishing homology because they will synapse randomly in a haploid organism undergoing meiosis. The general consensus is that the homology search is DNA-based, which accounts for the correct pairing of chromosome inversions, translocations, and alien chromosomes. In most organisms, including plants, a successful homologous chromosome pairing is linked to the progression of the meiotic recombination pathway, initiated by the action of the topoisomerase Spo11 to generate DNA double-strand breaks (DSBs). Mutants lacking Spo11 or other components of the meiotic recombination pathway that act at subsequent steps show serious defects in homologous chromosome pairing. In a number of species, the chromosome homology search and synapsis are closely coupled during the zygotene stage. Electron microscopy has revealed the presence of large numbers of small, electron-dense spheres associated with synapsing chromosomes during this stage. These nodules, called early recombination nodules, contain recombination enzymes and are predicted also to function in the chromosome homology search.

**MEIOTIC RECOMBINATION**

Homologous recombination fulfills a number of critical biological functions, including maintaining genetic diversity, repairing DSBs. Stabilizing interactions between homologous chromosomes in the form of chiasmata, promoting proper disjunction, healing a number of types of DNA damage, and removing undesirable mutational load. Because meiosis is a specialized type of cell division and the meiotic recombination machinery is largely derived from the machinery responsible for mitotic recombination and DNA repair in somatic cells, the meiotic and somatic recombination pathways share many components. However, a number of meiotic recombination-specific components also have been identified. Meiotic recombination is initiated by the introduction of DSBs on chromosomes by the topoisomerase Spo11 (Fig. 1). The DSBs are then resected and subsequently repaired by a protein complex containing two homologs of the *E. coli* RecA protein, Rad51 and Dmc1. These two recombination proteins are some of the most studied elements of meiotic recombination and have also been proposed to play roles in the pairing of homologous chromosomes. The Rad51/Dmc1 complex forms distinct foci on chromosomes during the meiotic prophase I, which are thought to mark the positions of DSBs. In maize, there are about 500 Rad51 foci in zygotene when...
Chromosomes are pairing, located mostly on unpaired chromosomes. By early pachytene, when pairing and synapsis are complete, there are only about 10–20 foci, which corresponds well to the number of meiotic crossovers in maize.

**METAPHASE I AND II CHROMOSOME SEGREGATION**

The reductive separation of homologous chromosomes at the first division of meiosis (MI) requires that homologous chromosomes recombine with each other and form bivalents. Since chiasmata hold the homologs together until the metaphase/anaphase transition during MI, failure to undergo recombination results in the inappropriate attachment of chromosomes to the spindle and their inaccurate segregation, leading to aneuploidy. Sister chromatid cohesion at the centromere and arms proximal to the chiasmata is maintained during the first meiotic division (MI) but is dissolved during the second meiotic division (MII), permitting the separation of sisters. During the MI reductive division, the kinetochores of both sister chromatids face the same spindle pole, and the kinetochores of one homolog face toward one pole while the kinetochores of the other homolog face the other pole. Often, sister kinetochores are fused to form a single structure. Following anaphase of MI, the two sisters end up at the same spindle pole. During the MII equational metaphase, sister kinetochores face the opposite spindle poles, ensuring that when sister chromatid cohesion is released at anaphase, the sister chromatids will move to opposite spindle poles and end up in different daughter cells.[3]

**THE IMPORTANCE OF UNDERSTANDING MEIOSIS FOR THE CROP SCIENTIST**

Meiosis requires DNA replication and chromosome condensation, homologue pairing and recombination, sister chromatid cohesion and homologue attachment, and spindle assembly and chromosome segregation. Many genes are expected to participate in these events, some of which will be unique to meiosis, whereas others are likely to be involved in other cellular processes. Therefore, understanding gene functions in meiosis will provide new insights into the molecular control of many basic cellular events in plants. Furthermore, knowledge about the genes controlling meiosis also has several potential applications in plant breeding. Such applications would include: 1) developing strategies for acquiring apomixis in maize and other grasses; 2) allowing manipulation of the level of genetic recombination in breeding programs, for example in wide hybrid crosses and for the introgression of quantitative trait loci (QTL) from exotic germplasm; 3) altering genetic incompatibility between species, thus permitting wide hybrid crosses and making it possible to select for desired traits from a broader gene pool; and 4) developing new methods for manipulating transgene integration in random or homologous transformation methods.

**CONCLUSION**

Meiosis is a highly specialized cell cycle leading to halving of the chromosome number per cell, which is required for the formation of gametes. Homologous chromosomes must pair and recombine, forming bivalents, in order for meiotic chromosome segregation to occur properly.

INTRODUCTION

Starting from amino acids phenylalanine or tyrosine, the phenylpropanoid pathway produces the majority of phenolic compounds found in nature. It has been estimated that approximately 20% of the carbon fixed by photosynthesis is directed into this pathway. More than 100,000 phenylpropanoid compounds have been identified from various species, making them one of the largest natural product families in the world. Many of these compounds are essential for normal plant growth and development. They also play important roles in defense against pathogens and plant–microbe/animal interactions. Some of the phenylpropanoid compounds have significant economic value that is important to human health or modern industries. Like metabolic engineering in other pathways, the majority of phenylpropanoid engineering research is aimed at achieving one of these three goals: 1) engineering as part of the effort to understand the metabolic pathway; 2) engineering to increase or decrease one or more specific compounds; and 3) engineering to introduce de novo biosynthesis of novel compounds in a particular species. This brief review has been focused on four directions of phenylpropanoid engineering based on their applications.

ENGINEERING TO ALTER FLOWER COLORS

Anthocyanins synthesized by the phenylpropanoid pathway are major components of flower and fruit colors. Because colored compounds serve as visual markers, many major discoveries in the history of plant biology were driven by studies related to the phenylpropanoid pathway. Examples include the purple pigment trait studied by Gregor Mendel in early genetic works during the 1900s; the red aleuron trait investigated by Barbara McClintock for her Nobel prize-winning discovery of transposons; and cosuppression of the chalcone synthase gene in petunia flowers that led to the flourishing of gene silencing and micro-RNA research (Fig. 1).

Silencing the expression of key anthocyanin biosynthetic enzymes resulted in white flowers or patches of white in various ornamental species that were normally colored. This novelty increased their market value. More economically significant has been the hunt for a blue rose since 1840, when the horticultural societies of Britain and Belgium offered a prize to the first person to produce a truly blue rose. A flavonoid 3′5′-hydroxylase (F3′5′H) is required for synthesizing purple and blue delphinidin-based pigments. Some species, such as roses and carnations, lack this enzyme in their genome. Therefore, it is impossible to produce a blue flower by traditional breeding despite the enormous efforts by generations of breeders. By introducing a petunia F3′5′H gene and a helper protein into a carnation through genetic transformation, Brugliera et al. produced a deep purple carnation in 2000.1 Currently, different variations of blue-color carnations dominate North American markets. Recently, Australian and Japanese researchers introduced three transformation constructs simultaneously into roses: a pansy F3′5′H gene to produce delphinidin, an anti-rose dihydroflavone reductase (DFR) gene that silences the endogenous DFR to produce a white background, and an iris DFR gene to make specific modifications of delphinidin. With this approach, the group announced a successful production of the world first blue rose in April 2005, claiming the Holy Grail of horticulture after a 165-year-long pursuit.

ENGINEERING TO IMPROVE FIBER QUALITIES

Lignins are phenolic polymers found primarily in secondary cell walls that add to the rigidity of stem tissue in terrestrial plants. Lignins constitute a significant proportion of plant biomass. Because the composition and structure of cell walls have a dramatic impact on the commercial value of raw materials, especially for the bio-ethanol and pulp industries, numerous strategies have been developed to reduce lignin contents in both woody plants and grasses. Reducing lignins will significantly reduce the energy cost, chemical input,
and toxic waste of pulp making, or increase the conversion efficiency of biomass used for fuel ethanol production.

The biosynthetic mechanisms of lignin monomers are well studied (Fig. 2). They are produced by a branch of the phenylpropanoid pathway involving enzyme p-coumarate 3-hydroxylase, hydroxycinnamoyl CoA:shikimate hydroxycinnamoyltransferase (CST), caffeic acid/5-hydroxyferulic acid O-methyltransferase (COMT), cinnamyl CoA reductase (CCR), cinnamate 4-hydroxylase (CAD) and others. Together, they convert p-coumaroyl CoA to p-coumaryl, coniferyl, and sinapyl alcohols. These monomers are transported to cell walls and crosslinked to form long chain lignins. Many lignin modifications thus targeted one or more of these enzymes (for a review, see Refs.[2,3] and references therein). For example, silencing of CST led to a 15% decrease in lignin content. Down-regulation of COMT by transformation with antisense constructs in alfalfa enhanced feed digestibility. Using transcription factors that coordinately regulate multiple steps of the pathway has also been carried out. One of the xylem-specific transcription factors (EgMyb2) isolated from Eucalyptus recognizes a conserved DNA motif in the CCR and CAD gene promoters. Over expression of EgMyb2 altered the lignin content in transgenic plants.

To target the crosslinking step, down-regulation of a tobacco cationic peroxidase in cell walls exhibited up to 50% reductions in lignin content without deleterious effects on plant development. In addition to manipulating plant enzymes, a fungal feruloyl-esterase that reduces the crosslinking of lignin polymers has been used to improve fiber quality as well. Genetically engineered trees with reduced lignin contents are currently in commercial production.

ENGINEERING TO ENHANCE PLANT DEFENSE

The majority of secondary metabolites produced by plants function as phytoalexins, which are inducible defense chemicals deterring bacterial and fungal pathogens. Engineering novel phytoalexins in heterologous plants provides a unique strategy to enhance plant innate defense systems. Previous experiments indicated that native pathogens may have difficulty in detoxifying novel phytoalexins (for a review, see Ref.[4] and references therein). For example, heterologous expression of stilbene synthase (STS) resulted in accumulation of the phytoalexin resveratrol in both tobacco and alfalfa and improved disease resistance toward the fungal pathogens Botrytis cinerea and Phoma medicaginis, respectively. On the other hand, silencing of key isoflavone biosynthetic enzyme isoflavone synthase (IFS) in soybean abolished isoflavonoid phytoalexin accumulation, and led to a drastic increase of disease symptoms after fungal pathogen Phytophthora sojae infection.[5] Not surprisingly, increasing flavonoid content in rice leaves and corn silks also significantly increases their resistance to a fungal and an insect pathogen, respectively.[4] Taken together, these results indicate that boosting crop phenylpropanoid phytoalexin production can reduce the use of chemical fungicide/insecticide, and may prepare crops to fight uncommon and novel pathogens.

ENGINEERING TO INCREASE FOOD NUTRITION

Many phenylpropanoid compounds have direct but complex effects on human health. For example, flavonoids and anthocyanins are strong antioxidants; epigallocatechin gallate and related catechins in green tea have been shown to reduce heart disease and strokes. Additionally, increasing condensed tannins in forage
stocks such as alfalfa may reduce the bloating of ruminant animals thus is useful in animal feed applications.

Isoflavones are predominantly produced by legumes and have been linked with alleviating postmenopausal symptoms and reducing breast and colon cancers by consumption of soybeans. The entry point enzyme IFS was used to transform non-legume species to initiate isoflavone production in cereal crops. A corn transcription factor was also transformed into soybean to alter isoflavone compositions. When combined with silencing of the F3H gene to block the competing pathway, this transcription factor increased soybean isoflavone levels by up to sixfold.

Similarly, to increase the antioxidant content of tomato, overexpression of a petunia chalcone isomerase in tomato skins led to a more than 80-fold increase in flavonoid levels. More interestingly, the above-mentioned resveratrol, which is found in red wine, was shown to function not only as an antioxidant, but also as a regulator of metabolism and longevity. Among a group of phenylpropanoid compounds tested, resveratrol most significantly extended life span of yeast, round worms, and fruit flies. Previously, Becker et al. coexpressed a poplar 4-coumaryl CoA ligase and a grape STS in yeast. When fed with proper substrates, the transgenic yeast was able to produce resveratrol directly. It will be interesting to see whether engineering de novo resveratrol biosynthesis in yeast or animal cells will lead to extended longevity.

**CONCLUSIONS**

The phenylpropanoid pathway is the best-studied and most engineered plant secondary pathway. In general, understanding the mechanism and regulation of biosynthetic processes is the foundation for engineering works. The rapid progress of genomics and metabolomics will certainly bring more scope and targets than the current handful of genes. However, metabolic pathways inside a cell are interconnected and may have complicated crosstalks. For example, tobacco lines with significantly reduced CCR expression resulted not only in an expected decrease in lignin content, but also in an increase in wall-associated xylose and glucose content, suggesting that the carbon flux between the two major cell-wall components maintains certain balances. Consequently, these pathway crosstalks may complicate the outcome of engineering attempts.

Adding another layer of complexity is the macro-molecular organization of biosynthetic enzymes. In metabolic pathways, specific interactions between sequential enzymes occur as dynamic complexes sometimes called “metabolons.” These multi-enzyme assemblies localize the accumulation of pathway intermediates and regulate competition for metabolites among branch pathways. Therefore, protein–protein interactions may regulate metabolic pathways beyond simple enzyme kinetic parameters and transcriptional controls. Metabolic channeling in the phenylpropanoid pathway has been demonstrated at various steps. These enzyme interactions play major roles in pathway regulation, and have to be taken into account to achieve optimum engineering results.

INTRODUCTION

Plants are traditional sources of organic materials used by humans for food and many industrial purposes.[1] The relevance of plants as food producers is clear, since their photosynthetic capacity ultimately represents the basis of life on our planet. Main industrially important compounds obtained from plants are (among others) wood, cotton, cork, and latex. Despite advances in chemical synthesis of organic molecules (i.e., plastics), many plant products are still unique. Thus, production of rubber of a certain quality only utilizes latex as a raw material.

In this scenario, the relevance of manipulating plants to improve their synthetic ability is clear. For years, selective breeding allowed increased productivity of crops, but with limitations. The development of genetic engineering expanded possibilities for improvement, as modification of plant metabolic pathways would allow the manipulation of the quantity and quality of natural products and also the synthesis of novel or heterologous compounds.[1,2]

The feasibility of plant transformation was firstly utilized for the production of genetically modified crops with enhanced resistance to herbicides and pathogens or with longer postharvest life.[3,4] These transgenic plants importantly affected agriculture, because they allowed reduced production costs and increased yields.[4] After these advances, efforts centered on modifying specific plant metabolic routes related to the synthetic proficiency of a particular crop.[3,4]

PLANTS AND METABOLIC ENGINEERING

Plant metabolic engineering is in the period of initial development. The rationale of genetic transformation of organisms requires the understanding of metabolism within the framework of metabolic control analysis, an issue not completely elucidated in plants.[2] Additionally, plant cells are highly compartmentalized, and the whole organism possesses both phototrophic and heterotrophic tissues. These facts determine complex metabolic networks, with partitioning of metabolites (and metabolic routes) intracellularly and between source and sink organs.[5] Despite this complexity, plant metabolic engineering has reached relevant goals and (more important) shows a highly promising future.[1,2] Key issues in the subject are the type of tissue (source or sink) and the intracellular compartment targeted for transformation.

PLANT PRODUCTIVITY IMPROVEMENT

Autotrophy of plants for fixing CO₂ into carbohydrates makes this process a key target for engineering in order to improve productivity. Possibilities include not only improving the carbon fixation process itself (in source tissues, see Fig. 1), but also increasing the carbon demand at sink organs where the product is finally accumulated (Fig. 2). Table 1 details the possibilities and advances made in the manipulation of carbon partitioning and allocation in plants.

Engineering Source Tissues

About 95% of plants (including many crops) are C₃ species that assimilate atmospheric CO₂ via the Calvin cycle or the C₃ photosynthetic pathway. C₃ plants utilize CO₂ with relatively low efficiency, since primary carbon fixation in the C₃ pathway is catalyzed by the chloroplastic enzyme ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco), which also utilizes O₂ as a substrate, leading to photorespiration that reduces (by up to 40%) photosynthetic efficiency (Fig. 1).[6]

Engineering of Rubisco to increase its ratio of carboxylase/oxygenase activity seems very unlikely, as predicted from the enzyme’s catalytic mechanism. The strategy to increase the carbon photoassimilation efficiency is now following the path traced by natural evolution: the addition of enzymatic steps to increase the CO₂ to O₂ ratio in the chloroplast (Fig. 1). Indeed, C₄ plants evolved a biochemical device that masters photorespiration.[2,6] Briefly, it comprises annexation of a metabolism (C₄ pathway) that pumps atmospheric CO₂ to the chloroplast. Additionally, leaves of C₄ plants have two types of photosynthetic cells (mesophyll and bundle sheath cells) that play a role in the integration of the C₃ cycle and the auxiliary pathway.[2,6]
The technology to introduce genes encoding enzymes of the C₄ pathway into C₃ plants was recently developed. Transgenic plants expressing C₄ enzymes at different levels exhibited alterations in carbon metabolism (Table 1). The overall view shows engineering of carbon photoassimilation metabolism at the starting point, with many questions to address in the near future about metabolic fluxes in transformed plants. Anyway, results obtained so far support the possibility of creating efficient CO₂-concentrating mechanisms, via metabolic engineering, to enhance photosynthetic efficiency of crops.

**Engineering Sink Tissues**

Metabolic engineering in plant sink tissues (Fig. 2), improving production of primary compounds, has successful examples in the manipulation of starch and fatty acid biosynthesis.

**Engineering Starch Metabolism**

Starch, a major product of photosynthesis, is synthesized in plastids of photosynthetic and nonphotosynthesizing cells from glucose-1-phosphate by the consecutive reactions of ADPglucose pyrophosphorylase (producing ADPglucose, the donor of glucosyl residues), starch synthase, and branching enzyme. The pathway is controlled at the level of ADPglucose pyrophosphorylase through allosteric regulation by 3-phosphoglycerate (activator) and Pi (inhibitor). A significant rise in starch accumulation in sink tissues was obtained by increasing ADPglucose pyrophosphorylase activity in plants transformed via the expression of an unregulated mutant of the enzyme from *Escherichia coli* (Table 1). This is a good example of the relevance of the understanding of enzyme kinetics and regulation for metabolic engineering. Based on the knowledge...
that this metabolic route is regulated at the level of ADPglucose pyrophosphorylase, its activity was permanently increased by expressing a mutant enzyme (lacking activator requirement for maximal activity) and thus enhancing ADPglucose and starch production.[2,7] Additionally, expression of the foreign gene was induced in storage tissue amyloplasts by using a tuber-specific promoter, as detailed in Table 1.[2,7,8] Transgenic products obtained by this methodology exhibited substantial improvement in their food quality traits. Thus, potato tubers with more starch (and solids) increased processing efficiency and resistance to cold storage, whereas transformed tomato fruits showed improved flavor.[1,8] Another objective is to engineer starch metabolism to modify the poly saccharide structure. Current strategies propose manipulating starch synthase and branching enzyme levels to alter contents of amylose and amylopectin and the branching degree in the latter polymer.[2,3]

**Engineering Lipid Biosynthesis**

Plants accumulate oils as triacylglycerols, with properties determined by the type of fatty acids they contain. Fatty acid biosynthesis occurs within plastids, by two-carbon elongation steps (initially derived from acetyl-CoA) catalyzed by a multienzyme complex. Length and desaturation, level of the product is determined by ketoacyl synthases, desaturases and thioesterases, which render the final fatty acid that is exported to the cytoplasm for triacylglycerol biosynthesis.[8] Cloning of genes encoding enzymes involved in fatty acid biosynthesis allowed the modification of oilseed

</table>
composition of certain plants by overexpression, antisense, and cosuppression technologies (Table 1).\(^1,8,9\) By this approach, oilseeds more resilient to oxidation, healthier for human consumption, or with industrial applications were obtained. This demonstrates the potentiality of plant metabolic engineering for managing production of renewable and biodegradable compounds.\(^1,9\) The next step envisions the modification of fatty acids to produce specific chemical structures, such as compounds containing epoxy functions or conjugated double bonds\(^1,2,4\)

**Improving Protein Quality and Vitamin Content**

Plants produce about 65% of the protein utilized for food by humans and livestock. Plant proteins are deficient in certain essential amino acids, mainly lysine, tryptophan, cysteine, and methionine.\(^8\) Table 1 shows strategies developed to correct this deficiency, by transferring genes between taxonomically distant plant species.

Manipulation of vitamin content in plants is an important issue where metabolic engineering may contribute to upgrading human health.\(^1,9\) Table 1 describes increases in vitamin E levels obtained in natural oils. This vitamin is an antioxidant whose presence in the human diet is relevant, especially under stress conditions such as those affecting populations in the developed world.\(^7\) Transgenic rice with high \(\beta\)-carotene content (Table 1) will also contribute to improving human health, mainly in developing countries where deficiency of vitamin A would be alleviated with the use of a major staple containing it.\(^7\)

**CONCLUDING REMARKS AND FUTURE PERSPECTIVES**

The wide metabolic diversity and the autotrophy exhibited by plants made them key tools in biotechnology. In the framework of metabolic engineering, this relevance is enhanced, as plants can be considered as potential factories for the production of compounds useful for food and industrial processes.\(^1,2\) Examples of the goals already reached and the potentiality of genetic manipulation for improving the quantity and quality of compounds synthesized and accumulated by plants have been detailed and are summarized in Table 1.

Two additional fields need consideration because of their current and future relevance in plant metabolic engineering (Fig. 2). First is production of secondary metabolites, as certain plants synthesize valuable chemicals (including alkaloids, anthocyanins, anthraquinones, polyphenols, steroids, and terpenoids) widely utilized as drugs, pigments, and pharmaceuticals.\(^1,2,7\) Secondly, plants are important biological systems for the production of heterologous compounds; they exhibit advantages for the production of recombinant proteins used for different industries (mainly pharmaceutical), as they synthesize fully folded functional products with low costs while avoiding ethical and safety problems.\(^2\)

Considering that the above analysis represents a relatively novel field, the future of plant metabolic engineering can be visualized as very promising. It is tempting to envision that the complete development of the technology and the better understanding of the biological process will make it possible to widely manipulate amounts and types of carbohydrates, oils, proteins, and many other compounds synthesized by plants.

INTRODUCTION

The term engineering refers to metabolic engineering, a field pioneered by microbial systems biologists and chemical engineers. Metabolic engineering is defined as "the directed improvement of product formation or cellular properties through the modification of specific biochemical reactions or the introduction of new ones through the use of recombinant DNA technology." This field has a strong foundation in mathematical analysis of metabolic fluxes and control in biochemical systems. Its emphasis is on understanding the function of biochemical reaction networks in vivo, thereby synthesizing information on the interactions of the various system components. Frequently this synthesis is achieved by an iterative cycle of genetic engineering, and by metabolic flux analysis using isotopic labeling. Metabolic modeling is employed to organize and conceptualize the data, facilitating the generation of new hypotheses guiding the next round of engineering. Plant metabolic engineering is in its infancy, but is receiving increased attention, as highlighted in the recent special issue of the journal "Metabolic Engineering," which is devoted to plants.

SECONDARY METABOLISM TERMINOLOGY

Secondary metabolism is a loose term generally referring to pathways that have no essential role in plant growth and development. Secondary metabolism is thus distinguished from primary metabolism, which refers to the network of catabolic and anabolic reactions essential for growth and development.[1] Plant metabolites typically referred to as secondary metabolites include a diverse array of alkaloids, phenylpropanoids, terpenoids, glucosinolates, and cyanogenic glucosides that may play roles in plant defense against pathogens and herbivores.[1–3] Their synthesis is often restricted to distinct plant taxonomic groups. The term natural products is preferred to describe this array of compounds.[1] Many are of great potential value as pharmaceuticals and/or precursors in the synthesis of industrial chemicals.[1,3] Because secondary metabolites are invariably derived from primary metabolites, effective engineering of secondary pathways cannot be readily undertaken without careful consideration of the competition between primary and secondary pathways.[4,5]

EXAMPLES OF METABOLIC ENGINEERING OF PATHWAYS OF PLANT SECONDARY METABOLISM

Recent advances in the metabolic engineering of plant secondary pathways will be illustrated by considering the natural products derived from tryptophan, tyrosine, and phenyalanine, the three aromatic amino acids (Fig. 1).

Alkaloids, Glucosinolates, and Cyanogenic Glucosides

Alkaloids, glucosinolates, and cyanogenic glucosides are strongly implicated in plant herbivore and pathogen defense.[1] Manipulation of fluxes to these compounds is of interest not only in modulating herbivore and pathogen resistance, but also in improving the nutritional quality of plants. Early successes in plant metabolic engineering involved overexpressing tryptophan decarboxylase (TDC) in canola, in order to divert flux away from the bitter indole glucosinolates, thus improving the quality of canola oil and making the product more palatable as an animal feed[1] (Fig. 1). Conversely, antisense downregulation of TDC has been used to eliminate indole alkaloid biosynthesis.[5] Overexpression of TDC in combination with other enzymes of the indole alkaloid pathway (e.g., stricosidine synthase) is being vigorously pursued as a strategy to manipulate flux to important terpenoid indole alkaloid compounds such as vinblastine.[1,3,5] Promising approaches also involve overexpression of transcription factors, resulting in induced levels of a number of genes of the pathway.[3,5] Daunting challenges in engineering metabolic flux to the terpenoid indole alkaloids will involve coordinating the supply of the indole moiety (derived from tryptophan) with the supply of...
Fig. 1 Plant secondary products derived from the amino acids tryptophan (Tryp), tyrosine (Tyr), and phenylalanine (Phe). Intermediate abbreviations appear on the next page.
the terpenoid precursors (derived from geraniol via the nonmevalonate pathway), and ensuring appropriate intracellular compartmentation and tissue-specific expression of the numerous pathway enzymes.\(^1\)\(^5\)

The pathway of synthesis of the indole glucosinolates in *Arabidopsis thaliana* proceeds via the catalytic action of O\(_2\) and NADPH-dependent cytochrome P450s acting on tryptophan and indole-3-acetaldoxime.\(^6\) CYP79B2 and CYP79B3 N-hydroxylate tryptophan, converting it to indole-3-acetaldoxime. CYP83B1 subsequently N-hydroxylates indole-3-acetaldoxime to its N-oxide\(^6\) (Fig. 1). Mutants (*superroot2* (sur2); *runt1*) of *Arabidopsis* are defective in CYP83B1 and have elevated levels of IAA, and decreased levels of indole glucosinolates. In contrast, overexpression of CYP83B1 causes a bushy, short phenotype consistent with reduced levels of IAA, suggesting that the glucosinolate pathway competes with the auxin biosynthesis pathway for the indole-3-acetaldoxime intermediate.\(^6\) These engineering efforts illustrate the difficulty in manipulating fluxes around the tryptophan node of metabolism without detrimental effects on plant growth via perturbations of auxin levels. This is further complicated by the existence of multiple pathways of auxin biosynthesis (both tryptophan-dependent and -independent) which may operate at different stages of plant development, as indicated by the dashed lines at the top of Fig. 1.\(^6\)

The cytochrome P450 catalyzing the conversion of tyrosine to p-hydroxyphenylacetaldexoxime in the biosynthesis of the cyanogenic glucoside dhurrin in sorghum, has been designated CYP79A1. p-hydroxyphenylacetaldoxime is subsequently converted to p-hydroxymandelonitrile by a second multifunctional P450 monooxygenase, CYP71E1. The final step in dhurrin synthesis in sorghum is the transformation of the labile cyanohydrin into a stable storage form by O-glucosylation of (S)-p-hydroxymandelonitrile at the cyano hydrin function, by a UDP-glucose:p-hydroxymandelonitrile-O-glucosyltransferase.\(^7\) (Fig. 1). The entire pathway for synthesis of dhurrin has been transferred from sorghum to *Arabidopsis thaliana* by expressing CYP79A1, CYP71E1 and UDP-glucose:p-hydroxymandelonitrile-O-glucosyltransferase.\(^7\) The accumulation of dhurrin in the transgenic plants confers resistance to the flea beetle.\(^7\) This clearly demonstrates the importance of cyanogenic glucosides in plant defense against insect herbivores, and it illustrates the potential for introduction of multiple genes to install a complete pathway in plants. Interestingly, when only CYP79A1 is expressed in *Arabidopsis*, the transgenic plants produce p-hydroxybenzyl glucosinolates.\(^7\) This is presumably because the intermediate p-hydroxyphenylacetaldoxime is recognized as a substrate by native glucosinolate-forming enzymes normally involved in indole and/or alky glucosinolate biosynthesis.

Considerable progress has been made in identifying the enzymes and genes involved in the production of pharmaceutically important isocoumarin alkaloids derived from tyrosine, including berberine, codeine, and morphine.\(^1\)\(^3\) Engineering of this pathway is currently focused on manipulating expression of tyrosine/DOPA decarboxylase (TYDC) and fluxes around the \((S)-\)reticuline node.\(^3\)

Phenylpropanoids

Phenylalanine is the starting point for the synthesis of a large number of phenylpropanoid secondary products, including flavonoids, isoflavonoids, and lignin. Examples of successful engineering of these pathways in plants include the introduction of chalcone reductase (CHR) in acyanic petunia to generate a novel, yellow flower color due to the accumulation of 6'-desoxychalcones[8] (Fig. 1), and the overexpression of transcription factors to globally activate or repress anthocyanin biosynthesis.[3] However, recent attempts to engineer isoflavone synthesis in Arabidopsis by introducing the soybean isoflavone synthase (IFS) gene have encountered a problem. It seems that IFS does not compete effectively with flavanone 3'-hydroxylase (F3H) for the naringenin substrate, perhaps because chalcone synthase (CHS), chalcone isomerase (CHI), and F3H may exist as a multienzyme complex, causing metabolite channeling.[9]

Lignin biosynthesis is a key branch-point from the phenylpropanoid pathway.[1,2] The lignin biosynthetic pathway has been recently clarified, and is now proposed to involve a 3'-hydroxylase (C3'H) acting on p-coumaroyl shikimate or p-coumaroyl quinate as substrates[10] (Fig. 1). The revised metabolic scheme for lignin biosynthesis is beginning to explain some of the phenotypes of altered lignin composition of mutants defective in the various metabolic steps, although our understanding of metabolic control in the pathway remains far from complete.[4] A detailed analysis of transgenic plants and mutants suggests that PAL, C4H and C3'H may be especially important in regulating carbon allocation in the pathway, with CCOMT, 4CL, CCR, F5H, and COMT playing subsidiary processing roles.[2]

FUTURE PROSPECTS

A significant number of the genes of plant primary and secondary metabolism have now been cloned, and they are being used in metabolic engineering experiments. Urgently needed are mathematical models that integrate the stoichiometric coefficients of the pathways with the kinetic properties of the enzymes encoded by these genes, and with the regulatory circuits that control both gene expression and enzyme activity. Such models will considerably aid future efforts devoted to rational flux manipulations of these pathways.

Milkweed: Commercial Applications

Herbert D. Knudsen
Natural Fibers Corporation, Ogallala, Nebraska, U.S.A.

INTRODUCTION

Milkweed, especially the Asclepias syriaca and Asclepias speciosa varieties, has excellent potential for commercialization as a new crop. Milkweed raw materials include pod floss, seed, and stem fiber. This article reviews the progress over the last 15 years in developing milkweed production, products, and markets to create a new agricultural business.

HISTORICAL

Asclepiadaceae is the milkweed plant family native to many countries in the world. The various species range from small shrubs, to vine covers, to plants ten feet tall. Two varieties—Asclepias syriaca and Asclepias speciosa—are particularly of interest because they are native to many areas in the United States, have erect stems four to six feet tall, and bear multiple large milkweed pods per stem.

Small-volume use of milkweed raw materials from native stands is widely reported. North American Indians used bast fibers from milkweed stems in clothing more than 1000 years ago. Flowers, sprouts, pods, and seeds have been used as food and medicine.

Boris Berkman, president of Milkweed Floss Corporation of America, organized the first effort to produce milkweed floss on a large scale. In 1943, the U.S. Government built a milkweed processing plant in Petoskey, Michigan as part of the war effort. This plant produced over two million pounds of milkweed floss for military life jackets in its one year of operation. Pods for the production facility were hand-collected in onion bags and shipped to Michigan. War volunteers throughout the United States collected milkweed pods under the slogan “Two bags save one life.” Berkman envisioned great potential for milkweed raw materials in industrial products, but no record of significant milkweed floss production or commercial use of milkweed in products after World War II has been found.

Standard Oil of Ohio conducted extensive research on growing milkweed and extracted the total harvested milkweed biomass with hexane to produce a crude oil substitute. Technically, the process was feasible, but the yield in terms of barrels per acre was too low to make the process economical. Standard Oil also worked with Kimberly-Clark to develop nonwoven products from milkweed floss, but no commercial products were produced.

In 1987, Standard Oil sold its milkweed venture to Natural Fibers Corporation (NFC), a privately held corporation formed to commercialize milkweed as a new crop. In 1990, a consumer products company, Ogallala Down Comforter Company, was formed as a subsidiary of NFC to make and sell goose down/milkweed floss comforters to specialty bedding stores in the United States and to the Four Seasons Hotels throughout the world.

MARKETS

The raw materials from milkweed are floss, seed, pod hulls, and stems, and markets for milkweed as a raw material needed to be created. The options are 1) to sell raw materials to others for their use in products they would develop; or 2) to develop, produce, and sell value-added products with these new raw materials. The downlike qualities of milkweed floss allowed for application in the down industry. Because of the up to 30-fold increase in value of down bedding compared to the milkweed floss content and because of the need to ensure a base load of floss demand, goose down/milkweed floss comforters and pillows as a new consumer product were produced by NFC internally and sold commercially.

Companies, research centers, and organizations have worked to develop milkweed raw material demand. Current projects include 1) working with Monarch butterfly organizations to expand milkweed habitat; 2) pressing milkweed seed to produce oil useful in cosmetics; 3) chopping milkweed floss to a fine powder for body care products; 4) developing milkweed floss nonwoven pads for bedding; 5) researching pulp made from milkweed for paper products; and 6) experimenting with milkweed biomass for nematode control in soil.

PRODUCTION FACILITY

To create a business at startup, a processing system for milkweed pods and a facility for manufacturing consumer products were needed. These issues were more important than cultivating milkweed, because wild collection of milkweed pods could produce enough dry pods to start and run the business for a number of years.
The processing system goal was to develop continuous mechanical separation of milkweed raw materials from dried pods. Boris Berkman’s plant in Michigan appeared to be continuous, but all production of milkweed raw materials for Standard Oil was done in a laborious batch process.

For the processor, information about Boris Berkman’s cylinder production system was collected, but experiments in similar, but smaller, cylindrical processing systems were not successful. A lower-technology approach of modifying a 1940 John Deere harvester, however, did work. See U.S. Patent 4,959,038. Since 1992, an automatic pod feeder was added, the floss hopper was eliminated in favor of direct bagging, and the footprint of the processor was reduced in a move to a new facility. The processor now operates to produce 40 pounds of floss per hour while recovering over 95% of the floss and seed. This processor is more than adequate for current needs, and the unit can be duplicated or modernized as raw material demand increases.

A second mechanical challenge was the blender. The fill developed for comforters and pillows was an intimate blend of milkweed floss and goose down. From bench scale data, a commercial-size blender was invented from wood and blowers. The blender was later upgraded to a cylindrical plastic chamber.

A final manufacturing issue was the production of comforters and pillows. A major issue was developing dependable comforter and pillow shell vendors and down suppliers.

**CULTIVATED PRODUCTION**

Cultivated production is still in the experimental stage, so milkweed pods are collected by hand from native stands in Nebraska, Wyoming, and Illinois. Wild sources provide time for our agricultural production research to develop proven farming practices. The estimated break-even point between the economics of wild collection and cultivated production is a cultivated yield of 50 pounds of floss per acre.

Cultivated production focused on maintaining milkweed in rows until 1996. However, because milkweed is a perennial plant that spreads through rhizomes, cultivation between rows disrupts the milkweed’s natural growing mechanism. With this understanding and the newly available preemergence herbicides that do not affect established milkweed, a change was made to plant broadcast stands of milkweed. Planting milkweed seed in stubble after early July wheat harvest protects the fragile seedlings from strong western Nebraska winds. The goal is to establish enough growth in half of a growing season so that the milkweed plant will produce pods the following year.

Systems for harvest and drying of milkweed pods were developed primarily by Kenneth Von Bargen and David Jones at the University of Nebraska. A row crop harvester for milkweed was modified from a New-Idea Uni-System ear corn harvester. The row crop harvester achieves 80% pod recovery in the broadcast stands of experimental fields.

Pods are generally harvested in September. During harvest, the harvester strips whole, green pods from the milkweed plant. The stalks are left behind and can be harvested by swathing and baling the dried stems. The pods are air dried and processed into raw materials. Raw materials can be stored under warehouse conditions for years.

A field life of 5–10 years is expected. Development of Roundup-ready soybeans is a major step forward in cultivated milkweed production. Before this development, a fallow year was required to eradicate the milkweed field before planting soybeans. Now milkweed can be eradicated while soybeans grow, and a production year is not lost.

Target economics provide the milkweed grower at least the same revenue as corn, with variable farming costs less than with corn. Contract farming would supply milkweed seed and technical advice to the farmer and would guarantee the purchase of the field’s output.

**CONCLUSION**

Increasing the demand for milkweed raw materials is the key challenge in developing the milkweed business. The strategy is to concentrate on higher-value (> $5 per pound of milkweed floss) and lower-volume uses. On the agricultural side, the goal is to develop growing technology to the point where innovative farmers can profitably grow the crop.

Minor Nutrients

Wolfgang Schmidt
Humboldt University, Berlin, Germany

INTRODUCTION

In contrast to major (macro) mineral nutrients, which (according to their function in osmoregulation, electrochemical equilibria, or as constituents of organic molecules) are required in relatively large amounts, micronutrients are needed in relatively small quantities; in some cases in only minute amounts. Micronutrients serve mainly as catalytic components of enzymes and play a structural role that is indispensable for enzymic function. Mineral nutrients that are required by higher plants for specific functions—such as Fe, Mn, Zn, Cu, B, Mo, Cl, and Ni—can be distinguished from those that have beneficial effects but are not needed by plants to complete a full life cycle and can be substituted by other nutrient elements or are needed by only few taxa, such as Na, Si, and Co. Research into micronutrients serves several goals. Knowledge of how micronutrients are acquired and transported helps in ameliorating the effects of reduction in crop yield caused by nutrient deficiencies, and improves our understanding of the distribution of species in natural habitats. In edible plant products there is a need for an adequate supply of those micronutrients essential for human and animal nutrition in order to eliminate the requirement for dietary supplements and postharvest treatments. Thus, increasing the metal content of our food helps to decrease health-threatening human deficiencies. A further aspect of the study of micronutrients concerns the use of plants for extracting metals from soil, for either phytoremediation or phytomining. Cleaning soils contaminated with trace metals by plants is an inexpensive method of soil remediation. Similarly, plants engineered to accumulate metals return an economic profit from waste rock.

Concerning the molecular background of micronutrient uptake and homeostasis, most knowledge comes from investigations into iron, zinc, manganese, and copper. Therefore, and due to space limitation, this article focuses on these nutrients. For a detailed overview of micronutrients, see the excellent textbook by Marschner and the recent review by Reid.

FUNCTION OF MICRONUTRIENTS IN PLANTS

Iron and copper are essential redox components in photosynthetic and respiratory electron transport and an indispensable cofactor in fundamental cellular processes. Due to its ability to pass readily between the divalent and trivalent oxidation states, iron participates in a wide range of electron transfer reactions that are essential for almost all organisms. Besides electron transport, copper is involved in free radical elimination, lignification, pollen formation, and hormone perception and signaling. Iron and copper metabolism appears to be interlinked in various respects. High levels of free Cu²⁺ causes iron deficiency, possibly by competition between Fe²⁺ and Cu²⁺ for binding sites on proteins or complexing compounds. In yeast and *Chlamydomonas*, copper deficiency also results in iron deficiency because copper is required for the synthesis of a multicopper oxidase that oxidizes ferrous iron prior to uptake of iron. The valency of zinc cannot be changed and the biological role of zinc is based on its tendency to form tetrahedral complexes. Zinc functions in the regulation of gene expression and is essential for a large number of enzymes, including alcohol dehydrogenase, carbonic anhydrase, and CuZn-superoxide dismutase. Manganese is required for a variety of essential processes, including light-induced oxygen evolution in photosynthesis and CO₂ fixation in C4 and Crassulacean acid metabolism (CAM) plants via phosphoenol-pyruvate carboxylase. In addition, manganese is important for the detoxification of free oxygen radicals via Mn-superoxide dismutase. Manganese is required for a variety of essential processes, including light-induced oxygen evolution in photosynthesis and CO₂ fixation in C4 and Crassulacean acid metabolism (CAM) plants via phosphoenol-pyruvate carboxylase. In addition, manganese is important for the detoxification of free oxygen radicals via Mn-superoxide dismutase. The function of molybdenum is related to valency change. Molybdenum plays an essential role in nitrate reduction and nitrogen fixation via nitrogenase. Chloride is essential for water splitting in PSII. A further function of chloride is associated with stomatal regulation. In species that lack functional chloroplasts for malate synthesis, Cl⁻ is transported as a counter anion for K⁺. Due to the ubiquitous presence of chloride in soils, toxicity is much more frequent than deficiency. Nickel is required in extremely low

amounts and is the most recent plant nutrient to be included in the list of essential elements. The only nickel-containing enzyme is urease. Boron has been implicated in a diverse array of functions and is dealt with in a separate article. Despite the fact that the requirement for boron is highest among the micronutrients on a molar basis, the role of boron is still not completely understood.

**UPTAKE AND TRANSPORT OF MICRONUTRIENTS**

Several classes of transporters that mediate the uptake of micronutrients from the soil solution and their distribution around the plant have been identified by sequence similarities and functional complementation. IRT1, the founding member of the ZRT-IRTlike proteins (ZIP) family, mediates iron uptake in Arabidopsis, and orthologs have been subsequently identified in other taxa. AtIRT1 can also transport manganese, zinc, and cobalt but not copper. Interestingly, the substrate specificity of IRT1 is defined by only few residues, offering the possibility of constructing plants with altered selectivity. Depending on the species, iron is either taken up as a divalent cation after reduction of the ferric form that prevails in most soils (strategy I) or as ferric chelate, complexed with plantborne siderophores with high affinity to ferric ions (phytosiderophores, PS, strategy II). Transporters of the natural resistance-associated macrophage protein (Nramp) family participate in iron uptake and iron homeostasis and have potential roles in the distribution of other metal cations, but their physiological functions are not yet clearly defined. Zinc is taken up as a divalent ion and accumulates in high amounts by some hyperaccumulators, such as Thlaspi caerulescens. ZIP proteins confer zinc uptake in yeast and appear to represent the major route of entry for zinc into plants. ZIP1 and ZIP3 are expressed in zinc deficient plants, can be downregulated by high zinc levels, indicating interaction between signalling cascades of various nutrients. Such cross talks have also been revealed by cDNA microarrays with plants grown in the absence of different essential nutrients, showing that several genes with potential regulatory roles are induced by deficiencies in various nutrients.

Copper enters the cell either complexed by organic ligands or as a free metal ion. Uptake of copper is mediated by a family of transporters named COPT1-COPT5, some members of which are repressed by excess copper. In yeast, Cu\(^{2+}\) must be reduced before uptake. Whether such a reduction is also required for copper uptake by plants is unclear. Manganese is taken up mainly as the free Mn\(^{2+}\) ion; a transporter specific for manganese has not been identified. Less is known concerning the uptake of those micronutrients that are taken up as anions. Molybdenum is transported across the plasma membrane as the MoO\(_4\)^{2-} anion. Chloride is taken up as a monovalent Cl\(^{-}\), most likely by an active process in symport with protons. No specific transporters involved in the uptake of micronutrient anions have been identified to date. Boron crosses membranes as an uncharged molecule. Besides simple permeation, boron is thought to be taken up by a transporter or via aquaporins.

**CELLULAR TRAFFICKING AND HOMEOSTASIS OF MICRONUTRIENTS**

The availability of micronutrients in the environment varies, necessitating regulated uptake systems to ensure that adequate amounts of essential ions are required. Knowledge of the mechanisms for maintaining cytoplasmic homeostasis of micronutrients is still fragmentary. The regulation of transporters mediating the uptake of metal cations appears to be complex, including both transcriptional and posttranslational control. For example, in transgenic plants overexpressing the iron transporter gene IRT1, the IRT1 product is rapidly degraded and represents a safety module when the iron concentration is increased rapidly. Moreover, IRT1, which is not expressed in zinc deficient plants, can be downregulated by high zinc levels, indicating interaction between signalling cascades of various nutrients. Such cross talks have also been revealed by cDNA microarrays with plants grown in the absence of different essential nutrients, showing that several genes with potential regulatory roles are induced by deficiencies in various nutrients.

To prevent toxicity, metal cations have to be chelated after entering the cells. This is mainly achieved by peptides such as phytochelatin and metallothioneins, organic acids, polyphenolics, and an array of yet unidentified low molecular weight anionic ligands. A specific role in the distribution of heavy metals has been suggested for the amino acid nicotianamine (NA). In some plants, NA concentrations are considerably increased by high external copper and iron, pointing to the role of NA in the detoxification of excess metals. Immunostaining of the NA–Fe complex has revealed that labelling density was highest in the cytoplasm under adequate iron supply, whereas most of the labelling was present in the vacuole when the plants were iron loaded. Accordingly, sequestration of iron and possibly other metals into the vacuole appears to represent a mechanism regulating the cytoplasmic level of metal ions. Besides Nramps, members of the cation diffusion facilitator (CDF) family, yellow striplike (YSL) transporters, and heavy metal (CPx-type) ATPases have been implicated in the uptake, efflux, and sequestration of metal cations, but (with few exceptions) a specific physiological function of these transporters has not yet been proven.

**LONG-DISTANCE TRANSPORT**

Little is known about how metals are transported over long distances, either from roots to the shoot after uptake
from the soil via the xylem or, during remobilization, from source to sink in the phloem. Generally, metal micronutrients are complexed by ligands to decrease interaction with charged groups during transport. In the xylem, iron is complexed with citrate as the $\text{FeCit}_3^{2−}$ ion in a 1:1 ratio. Zinc and manganese are also most likely bound by citrate during xylem transport. Unlike other heavy metals, copper appears to be bound by NA during translocation, a complex with an extremely high stability constant. Other low molecular-weight ligands that have been suggested to function in xylem transport are histidine and phytosiderophores of the mugineic acid family. Co-loading of NA and micronutrients into the phloem supports a role for NA in this process, but a function of NA as a ligand for phloem transport has not been confirmed. A protein with high affinity for iron that can also complex copper, zinc, and manganese in vitro has recently been isolated from *Ricinus* phloem exudates, representing the first identified micronutrient ligand mediating phloem-mediated long-distance transport.[12]

**CONCLUSION**

Although unraveling the intra- and intercellular transport of micronutrients has recently begun at the molecular level, many important questions concerning the mechanisms underlying uptake, trafficking, and sequestration still remain unanswered. Little is known about how the level of micronutrients—either within the cell or in its immediate vicinity—is sensed and how this signal is translated to adjust uptake and transport within the cell. The elucidation of the mechanisms that determine the concentration and distribution of micronutrients in plants opens new avenues to deepen our understanding of both basic and applied aspects of plant mineral nutrition as diverse as the autecology of species and the improvement of human nutrition.

Mitochondrial Respiration

Agepati S. Raghavendra
University of Hyderabad, Hyderabad, India

INTRODUCTION

Respiratory metabolism occurs in two compartments of plant cells: cytoplasm and mitochondria. Cytoplasm is the site of glycolysis, which produces pyruvate from glucose. The mitochondria carry out further oxidation of pyruvate to CO₂ and H₂O, and they produce adenosine triphosphate (ATP).

Mitochondria are threadlike or rod-shaped organelles, enveloped by an outer and an inner membrane. The space between these two membranes is called intermembrane space. The outer membrane is unselective in permeability, but may be regulatory because of porins (pore-forming proteins). The inner membrane is highly selective and directs metabolite movement through translocators. The inner membrane encloses the granular matrix and has invaginations called cristae. Besides the enzymes of the tricarboxylic acid (TCA) cycle, the matrix contains mtDNA and machinery for protein synthesis and fatty acid metabolism. The components of oxidative electron transport and phosphorylation are located in the inner membrane.

Mitochondrial respiration is most important in terms of contribution, complexity, regulation, and interaction with other organelles. Of about 64 molecules of ATP generated from the oxidation of one molecule of sucrose, 56 molecules of ATP are produced in mitochondria. Besides meeting cellular energy demands, mitochondrial respiration provides the carbon skeletons for primary and secondary metabolism, forms a link in interorganelle interaction, and helps in the homeostasis of redox in cytoplasm.¹,²

SUBSTRATES AND PRODUCTS

Mitochondrial respiration consists of three steps: the TCA cycle, electron transport, and oxidative phosphorylation.¹,² The first step is oxidation of substrates like pyruvate or malate through the TCA cycle to generate reduced nicotinamide adenine dinucleotide (NADH) and reduced flavin adenine dinucleotide (FADH₂), which are oxidized through electron transport to generate a proton electrochemical gradient across the inner membrane. In the last step, the energy from the proton gradient is used for ATP formation through oxidative phosphorylation.

The substrates for mitochondrial respiration in plant cells range from pyruvate, malate, glutamate, succinate, and glycine, coming from the cytoplasm, chloroplasts, glyoxysomes, or peroxisomes.²,³ The predominance of substrate depends on the developmental stage of the organ, the type of tissue, and the presence of light. Pyruvate, malate, or succinate is oxidized through the TCA cycle to yield NADH or FADH₂, CO₂, and H₂O. Glutamate is converted to 2-oxoglutarate and fed into the TCA cycle. Glycine is oxidized to serine and sent into peroxisomes. NADH and FADH₂ generated during the oxidation of substrates are utilized in the electron transport to produce ATP.

The final products of mitochondrial respiration are ATP, CO₂, and H₂O. However, intermediates of the TCA cycle are exported to provide carbon skeletons for nitrate assimilation and other processes.

TCA CYCLE

The major activity of mitochondria is to form citrate, by condensation of acetyl CoA (from pyruvate) and oxaloacetate, and oxidize it through the TCA cycle (Fig. 1). Pyruvate is oxidized (to acetyl CoA) by pyruvate dehydrogenase, a multienzyme complex composed of three components: pyruvate dehydrogenase, dihydrolipoyl transacetylase, and dihydrolipoyl dehydrogenase. Acetyl CoA condenses with oxaloacetate to form citrate, an irreversible reaction catalyzed by citrate synthase. The enzyme aconitase isomerizes citrate to isocitrate, which is oxidized to 2-oxoglutarate by isocitrate dehydrogenase. Another multienzyme complex, 2-oxoglutarate dehydrogenase oxidizes 2-oxoglutarate to succinyl CoA. The hydrolysis of succinyl CoA by succinyl CoA thiokinase yields succinate and ATP. The next step of succinate oxidation to fumarate is catalyzed by succinate dehydrogenase (also known as Complex II), an enzyme bound to the inner membrane. Fumarate is converted to malate by fumarase. Malate is oxidized to oxaloacetate by NAD-malate dehydrogenase to complete the cycle.¹,²

The complete operation of the TCA cycle does not always occur, because some intermediates are exported to meet the carbon demands of cytoplasm.²,³ For example, citrate and 2-oxoglutarate are needed for nitrate assimilation. It becomes essential to replenish the intermediates...
of the TCA cycle. Mitochondria, therefore, import malate (formed from oxaloacetate through PEP carboxylase), glutamate (formed from nitrate assimilation and present in high quantities in the cytoplasm), and glycine (formed in photorespiration). Glycine is the major substrate for mitochondrial respiration in leaves under light.

**ELECTRON TRANSPORT CHAIN**

The oxidative electron transport chain, located in the mitochondrial inner membrane, is formed of complexes, as in chloroplasts.  

The mitochondrial electron transport chain consists of four modules: NADH-dehydrogenase complex (Complex I), the cyt-b/c complex (Complex III), and the terminal cyt-a/a₃ complex (Complex IV). The oxidation of succinate is initiated by the succinate dehydrogenase (Complex II), and the electrons pass through Complexes II and IV (Fig. 2).

Complex I accepts electrons from NADH and passes them on to ubiquinone within the membrane. The ubiquinone is reduced and traverses across the inner membrane to reduce the cyt-b/c complex and to pull protons from the matrix side into the intermembrane space. The NADH dehydrogenase complex is made up of more than 40 subunits. Complex II is the smallest and has 4 subunits. The cyt-b/c complex is made up of 9–11 subunits. The reduced cytochrome c diffuses along the surface of the inner membrane to reach and reduce Complex IV (earlier known as cyt-a/a₃, consisting of 7–9 subunits), which is in turn oxidized by O₂. Protons move from the matrix into the intermembrane space during the reduction/oxidation of cyt-a/a₃.

Plant mitochondria can oxidize NAD(P)H on the cytoplasmic side, by an external NAD(P)H dehydrogenase, distinct from Complex I. The external NAD(P)H dehydrogenase is regulated by calcium and the levels of NADH/NADPH.  

---

Fig. 1  Overview of the oxidation of pyruvate through the TCA cycle. The dotted lines represent the boundaries of mitochondria; enzymes are indicated by italics; and the inputs and outputs are indicated by gray broken arrows.
OXIDATIVE PHOSPHORYLATION

The mitochondrial electron transport creates an electrochemical proton gradient and facilitates ATP formation, as in chloroplasts. The oxidation of NADH/FADH drives protons from the matrix into the intermembrane space, creating a strong proton gradient (the intermembrane space being acidic) and depolarizing the membrane\(^2,4\).

Protons diffuse back into the matrix through the F\(_0\)-F\(_1\)-ATP synthase complex. The F\(_0\)-F\(_1\)-ATP synthase of mitochondria is a multienzyme complex with two major components. The F\(_0\) is membrane-embedded and is the proton channel. The F\(_1\) is peripheral, extends as a stalk into the matrix, and is the site of ATP formation. F\(_1\) contains five different subunits in a ratio of \(a_3\beta_3\gamma_1\delta_1\), while F\(_0\) has three, with a composition of \(a_1b_2c_{10-12}\).

The function of F\(_0\)-F\(_1\) is quite fascinating. F\(_1\) can synthesize ATP from ADP and Pi without additional energy, but a change in conformation driven by H\(^+\) transport across the complex is needed to release ATP bound to the ATP synthase. The oxidation of each NADH molecule through the electron transport and phosphorylation yields 2.5 molecules of ATP and the oxidation of each of FADH molecule yields 1.5 of ATP.

ALTERNATIVE PATHWAY OF OXIDATIVE ELECTRON TRANSPORT

The mitochondrial respiration in plants is not completely inhibited by compounds such as cyanide, because their electron transport occurs through two different routes: the cyanide-sensitive cytochrome path and a cyanide-insensitive alternative path. The alternative pathway is facilitated by an alternative oxidase (a 32 kDa polypeptide), which has been isolated, cloned, and characterized in detail\(^5,6\).

Both pathways use Complex I/II and diverge at the site of ubiquinone (Fig. 2). Since these electrons do not use Complex III or IV, the extent of ATP formed from NADH through the alternative pathway is much less than that through the cytochrome pathway. Most of the energy is released as heat. The main function of the alternative electron transport is to oxidize surplus NADH (even if without ATP formation) and to produce heat. Since the alternative oxidase expression is boosted under environmental stress, it also may have other functions.

FUNCTION AND REGULATION OF MITOCHONDRIAL RESPIRATION

Unlike chloroplasts, mitochondria export ATP to the cytoplasm at high rates through an adenylate translocator, complemented by a phosphate translocator. The translocators are specialized proteins of the inner membrane of mitochondria that facilitate the movement of key metabolites. Among the translocators (and the compounds translocated) present on the inner membrane of mitochondria are malate or dicarboxylate (malate/Pi), 2-oxoglutarate (2-oxoglutarate/malate), citrate/tricarboxylate (citrate/dicarboxylate), oxaloacetate (oxaloacetate/malate), pyruvate (pyruvate/OH\(^-\)), and glutamate (glutamate/aspartate). The presence of a glycine/serine translocator is expected.

---

**Fig. 2** Electron flow from NADH or FADH through the mitochondrial electron transport chain involving either the cytochrome pathway (Complex IV or CytOX) or the alternative pathway (alternative oxidase, AOX). Plant mitochondria also have an external NAD(P) dehydrogenase.
The operation of the TCA cycle and oxidative electron transport are highly regulated[1,2,4] by the energy status (relative levels of ATP and ADP) of the cell and the redox status of mitochondria (the levels of NADH) and acetyl-CoA. Increase in ATP promotes the phosphorylation and inactivation of pyruvate dehydrogenase. Similarly, increase in NADH causes feedback inhibition of dehydrogenases. Thus the turnover of the TCA cycle depends on the rate of NADH reoxidation by electron transport and the balance between ATP production and utilization. The availability of substrates (e.g., carbohydrate) is important. The regulation of oxidative electron transport by the availability of ADP and Pi is well known ("respiratory control"). Further, the movement of ATP/ADP/Pi into and out of mitochondria is modulated by the electrochemical proton gradient.

The alternative oxidase facilitates a distribution of electrons through the oxidative electron transport. The extent of flow through cytochrome or alternative pathways is modulated by metabolites such as pyruvate and reducing agents such as dithiothreitol[5,6]. The operation of alternative pathways is regulated by environmental stresses and factors modulating the carbon metabolism. Several metabolic inhibitors are available which block or inhibit different steps of the TCA cycle, translocators, oxidative electron transport, or ATP formation (Table 1).

### IMPORTANCE IN PHOTOSYNTHESIS AND INTERORGANELLE INTERACTION

In plants, photorespiration is essential for retrieving half of the carbon diverted through the Rubisco oxygenase activity, with mitochondrial oxidation of glycine as the key. Mitochondria are the site of malate decarboxylation in NAD-malic enzyme type C₄ and CAM plants. Thus, mitochondrial respiration is essential for C₃-, C₄-, and CAM photosyntheses.[2,3]

Mitochondria interact beneficially with chloroplasts and peroxisomes.[7] Chloroplasts supply the substrates for mitochondria, which in turn dissipate the excess reductants generated in chloroplasts. Such cooperation optimizes the photosynthetic carbon assimilation and protects chloroplasts against photoinhibition. Another process, which involves the cooperation of mitochondria with chloroplasts and cytoplasm, is nitrate assimilation.

### CONCLUSION

The focus of plant science research has shifted from physiology and biochemistry to the areas of molecular biology and biotechnology. Stupendous progress has occurred in understanding the molecular biology of the function and regulation of mitochondrial respiration. Genomics of plant mitochondria are well known, and the present focus is on proteomics.[8] Genetic manipulation of enzymes, such as citrate synthase, has been done.[9] Mutants (e.g., those deficient in some components of F₀-F₁) have long been used to analyze the mitochondrial function.[10] The mitochondrial transformation is bound to catch up soon with chloroplast transformation.

Mitosis

Dénes Dudits
Attila Feher
Hungarian Academy of Sciences, Szeged, Hungary

INTRODUCTION

Duplication of somatic plant cells by mitotic division is a fundamental cellular function that provides a continuous supply of cells to create the plant body during the life cycle. Mitosis ensures the faithful transmission of genetic information by packaging replicated DNA strands into high-order chromatin structures leading to the condensation of mitotic chromosomes that are distributed into the daughter cells. Chromosome organization is an active condensation/decondensation process that depends on histone H3 phosphorylation and the functions of topoisomerases and condensin complexes. Parallel with chromosome condensation, organization of microtubule (MT) arrays, such as the plant-specific preprophase bands (PPB), the phragmoplast, and the mitotic spindle provide the apparatus for chromosome separation and new cell plate formation in cytokinesis. The MT function is dependent on the dynamic structure of tubulins and the large number of MT-associated proteins (MAPs). Cyclin-dependent kinases (CDKs) and various members of plant mitogen-activated protein kinases (MAPKs) act as mitotic regulators in cooperation with phosphatases (PP2A). The transition from metaphase to anaphase is controlled by the degradation of cohesin by separase. This cysteine protease can be activated by degradation of an inhibitor protein separin, through the anaphase-promoting complex (APC) as a specific ubiquitin ligase complex. During cytokinesis, the phragmoplast serves as a scaffold for the maturation of the vesicle fusion-generated network binding of the new cell wall.

VISUALIZATION OF STRUCTURAL CHANGES IN THE NUCLEUS AND MICROTUBULES OF MITOTIC PLANT CELLS

The series of micrographs in Fig. 1 highlight the major mitotic events and reveal the coordination between chromosome dynamics and MT organization. The DNA was stained by DAPI and the MTs were visualized by fluorescent labeled antitubulin antibodies.

GENE EXPRESSION PROFILES DURING G2-M PROGRESSION

The identification of transcriptionally active genes in mitotic cells provides essential information about the functionally important molecules and their roles in mitosis.
The recent genomewide transcriptome analysis of synchronized tobacco and Arabidopsis cells highlighted a set of genes that are preferentially expressed in G2 and mitotic phases of the cell cycle. In tobacco cells, the cDNA-AFLP-based transcript profiling revealed more than 1300 transcript tags with significant modulation during the cell cycle. The G2 cells exhibited 16% of these tags enriched in transcriptional factors. Mitotic cells provided the largest group of cell cycle tags (53%) representing genes with functions in cell cycle control (4.17%), RNA processing (5.37%), protein synthesis (8.65%), protein phosphorylation (5.67%), proteolysis (5.07%), cytoskeleton (11.34%), cell wall (7.46%), and transport secretion (6.26%). A large portion (33.43%) of tags corresponded to proteins with unknown function. By the use of an Affymetrix Gene Array in synchronized Arabidopsis cells, nearly 500 gene signals (12% of total expressed genes) were identified that have a significant cell cycle phase-dependent fluctuation in expression. A high portion (30%) of these genes showed a peak of expression in the G2 phase and mitosis. These data convincingly show that transcriptional control has a critical role in regulation of mitotic functions. Furthermore, the list of genes expressed during mitosis and the prediction of the encoded proteins can provide a comprehensive insight into mitosis at the molecular level. In addition to mitotic B-type cyclins, plant-specific CDKs (in Arabidopsis: CDKB1 and CDKB2; in alfalfa: cdc2MsD, cdc2MsF) with unique cyclin-binding motifs (PPTALRE, PPTTLRE) exhibit clear transcript accumulation in G2/M cells. Plants differ from yeasts and animals in this feature. Similarly, the β-tubulin genes from plants are highly induced in G2 and early M-phase, whereas the tubulin-gene expression fluctuates moderately during the yeast cell cycle. The class of kinesin genes showed mitosis-linked expression profiles. The Arabidopsis homologue of the CDC20 gene from budding yeast was actively transcribed in mitotic cells. The encoded protein is involved in the activation of the anaphase-promoting complex. The mitotic function of various kinases such as NPK1, MAPKs with a role in

Fig. 1  Components of mitotic events in plant cells. In alfalfa cells the DNA is stained with DAPI (orange) and the microtubules are visualized by fluorescent-labeled antitubulin antibodies (green). phragmosplast and cell plate growth, or the homologue of Aurora kinase involved in chromosome segregation and cytokinesis, can be inferred from the gene expression profile. The regulatory role of protein phosphorylation is also emphasized by the activity of genes encoding various phosphatases (e.g., protein phosphatase 2C). Activity of the ubiquitin-proteasome complexes during mitosis can be seen from expression of genes of the M-phase-specific, protein-degradation system. The hormonal control of mitosis can be related to the high level of expression of histidine kinase gene encoding the cytokinin receptor CRE1. The mitotic peak in expression of auxin-related genes (IAA17; At2g46690) is in accordance with the auxin dependence of this cell cycle phase.

As extended analyses of cell cycle, phase-dependent gene that expression patterns demonstrate, significant number of plant genes are under a tight transcriptional control. The Mitosis-Specific Activator (MSA) cis element in promoters of various B-type cyclins and the tobacco kinesin-like protein genes (NACK 1,2) has been identified as responsible motif for the G2/M phase-specific gene expression. The Myb-related transcription factors (NtmybA1 and A2) with three imperfect repeats in the DNA-binding domain can activate while the Ntmyb factor represses transcript accumulation from genes with MSA-promoter element.

MOLECULAR MECHANISMS UNDERLYING SISTER CHROMATID COHESION AND CHROMOSOME CONDENSATION

The two initial phases in chromosome organization include cohesion and condensation—both events based on distinct, yet structurally similar proteins forming the cohesin and condensin complexes. These components of mitotic chromosome dynamics and functions show high evolutionary conservation from yeast to vertebrates, and recent studies on the titan (ttn) mutants of Arabidopsis demonstrate the functional significance of plant cohesin and condensin as well.

The duplicated sister chromatids produced by replication of chromosomal DNA are tightly paired, at both the centromere and along the arms throughout the G2 phase and during condensation of chromosomes. The cohesin complex, which physically holds sister chromatids together, involves the SMC1 and SMC3 proteins (structural maintenance of chromosomes) in yeast, Aspergillus, Xenopus, and humans. In Arabidopsis, a single orthologue of these genes has been identified and the SMC1 (ttn8) and SMC3 (ttn7) knockouts show a strong titan phenotype with defects in embryo and endosperm development.

In mitotic plant chromosomes, condensation is a highly ordered and active process that starts during early prophase from the centromeric region. The complete remodelling of the chromatin structure results in a high degree of DNA packing into tightly folded chromatin. The condensation process depends on histone modifications (phosphorylation, de-ubiquitination) and the activity of topoisomerases and condensin complexes. In mitotically dividing cells, the process of chromosome condensation has been shown to be coupled with phosphorylation of histone H3. Mitotic CDK complexes and serine/threonine phosphatases can alter the degree of chromosome condensation, as demonstrated by experiments based on the microinjection of kinase complexes or treatment with phosphatase inhibitors (endothall, sodium vanadate, cantharidin). The phenomenon of premature chromosome condensation (PCC) can be induced by fusion of mitotic and interphase plant protoplasts or by exposing cells to phosphatase inhibitors.

The functional role of topoisomerase II during the condensation process is to induce super coils into the DNA helix that allow an increase in the packing density of DNA. Treatment of plant cells with inhibitors of this enzyme aborted the chromosome condensation. The presence of an other topoisomerase (type I) is required for the function of the multisubunit condensin complex that organizes the topology of DNA loops in the chromosomes. The core condensin complex consists of two structural maintenance of chromosome (SMC) subunits—SMC2 and SMC4—that form the 13S condensin complex, and includes three other proteins (Cnd1–Cnd3). The SMC core complex can bind to naked DNA and exhibits ATPase activity that is increased in association with regulatory subcomplex formed by Cnd proteins. In Arabidopsis, the TTN3 gene corresponds to a SMC2 condensin homologue expressed in most of the plant organs. Apart from CDKs, other enzymes such as the Aurora B kinase can be required for condensin activity during metaphase. A plant orthologue of this kinase gene has been found in transcript-profiling experiments with cultured tobacco cells.

As shown by electron micrographs in Fig. 2., condensed mitotic plant chromosomes are organized into chromosome arms separated by a centromeric region. Sister chromatids of metaphase chromosomes are joined at the centromere where the centromeric DNA is closely associated with a protein-rich structure called the kinetochore, the attachment site for MTs. At the end of the linear chromosome, telomeres protect the chromosome from shortening. The length of repeated telomeric sequences (TTTAGGG in Arabidopsis) may change during development. Telomeras can copy several telomere repeats with the help of complementary RNA molecules.
In coordination with the condensation of chromosomes, the highly dynamic structure of the MTs is organized in dividing plant cells to serve as one of the key functional components for segregation of chromosomes. The heterodimers of α- and β-tubulin subunits constantly assemble, disassemble, and rearrange (polymerize/depolymerize) during the organization of MT arrays such as the preprophase bands, the mitotic spindle and the phragmoplast (Fig. 1). The MT organization and dynamics require the functional contribution of a large number of MT-associated proteins. The ATP-dependent motor proteins move unidirectionally along the surface of MTs and function as transporters or MT organizers. The kinesin-like motor proteins such as KCBP/2-WICHEL can induce the transient and local stabilization of MTs to be rearranged or focused. Mutation in the TANGLED1 (TAN1) gene causes misorientation of MT arrays. This protein is associated with mitotic MT arrays and repeats in cytokinesis.

The central role of different MAPs in phragmoplast organization and cytokinesis is shown by the characteristics of cell division mutants or immunolocalization studies. The Arabidopsis Microtubule Organization (MOR1) protein and its homologue, the tobacco MT-bundling protein (TMBP200), participate in the organization of MT arrays (e.g., by cross-bridging between phragmoplast MTs). Inhibition of a motor protein called TKRP15 interferes with translocation of phragmoplast MTs. One of the phragmoplast-localized, kinesin-related proteins of Arabidopsis (AtPAKRP2) has been suggested to act as transporter of Golgi-derived vesicles to the newly forming division plate.

Several essential mitotic events including MT dynamics are under a defined phosphorylation control, based on a series of kinases and phosphatases with regulatory and/or coordinatory function. The pivotal role of CDKs in mitotic plant cells can be concluded from G2/M phasespecific expression of the corresponding genes, identification of mitotic kinase complexes, protein interaction, and immunolocalization studies. In synchronized G2/M alfalfa cells, at least three types of Cdc2-related kinase complexes can be detected with characteristic timing of activity peaks (Fig. 1). The Cdc2MsA/B kinases are highly active in mid-G2 phase, whereas the Cdc2MsD kinase activity peaks before the start of mitosis. The CdcMsF kinase represents a typical mitotic kinase.

The alfalfa Cdc2MsD and F kinases have Arabidopsis orthologues (CDKB1 and CDKB2) and exhibit plant-specific, cyclin-binding motives (PPTALRE or PPTTLRE) instead of the PSTAIRE sequence element. The alfalfa Cdc2MsF mitotic kinase was shown to be colocalized with MTs in all mitotic stages. In general, the B-type cyclins are considered regulators of mitotic CDKs; however, a role for A-type and D-type cyclins can be inferred from protein-interaction studies. Gene predictions based on sequence data of the Arabidopsis genome suggest 10 A-type cyclins, 9 B-type cyclins, and 10 D-type cyclins. As far as the number of cyclin gene variants and kinase complexes is concerned, the mitotic cell cycle control machinery in plants shows higher complexity than in animals; however, the specificity and redundancy in cyclin gene functions have not been elucidated so far. The formation of active CDK complexes is dependent on the
phosphorylation of selected amino-acid residues of the interacting partners. The CDK-activating kinases (CAKs) and inhibitory phosphorylation by the Wee1 (Mik1-type) kinases can alter the CDK functions that are also controlled by the set of inhibitor proteins. The Kip-related proteins (in Arabidopsis, KRP1-KRP7) can differentially regulate the various CDK complexes. The list of kinases involved in the control of mitosis is not restricted to the CDKs. Various members of plant mitogen-activated protein kinase (MAPK) cascades can contribute to the establishment and function of the phragmoplast during cytokinesis. Nucleus-and phragmoplast-localized Protein Kinase 1 (NPK1) activity is required for expansion of both the cell plate and the phragmoplast. Other MAPKs, such as p43Ntf6 from tobacco and MMK3 from alfalfa, are activated during cytokinesis. The Arabidopsis HINKEL (HIK) protein and its orthologue in tobacco, the Nicotiana protein kinase 1 (NPK1)-activating kinase-like protein 1 (NACK1), can initiate a signaling cascade involved in the cytokinesis.

An increasing number of experimental data support the significance of phosphatases as counteracting enzymes of kinases in regulating mitotic events in plant cells. The formation of active CDK complexes requires the removal of inhibitory phosphate from the Tyr-14 and Thr-15 residues of the CDKs. Cdc25-related phosphatases can activate CDKs in yeast, Drosophila, and in mammalian cells. Attempts to identify plant orthologues of these phosphatases are expected to be successful. However, expression of the yeast Cdc25 enzyme in tobacco transformants caused cytokinin-independent premature mitosis, reduced cell size, and altered lateral root development. In general, cytokinins are needed to form an active CDK complex. The role of serine/threonine phosphatases (e.g., PP2A) in MT organization can be concluded from inhibitor experiments. In endothall-treated alfalfa cells, the formation of PPBs and the phragmoplast is disturbed, and the premature polarization of the mitotic spindle is coupled with the early activation of mitotic Cdc2MsF kinase. Mutation in the Arabidopsis TONNEAU2 (TON2)/FASS gene encoding a putative B-regulatory subunit of PP2A phosphatases causes similar abnormalities in mitosis.

CD clan of cysteine proteases. The precise timing of separase activation is crucial, because it can occur only after the formation of bipolar attachments between the sister chromatids and the spindle MTs. This tightly controlled regulatory process includes an inhibitory protein called securin that blocks separase activity until the Anaphase-Promoting Complex (APC), a specific ubiquitin-ligase complex, links a polyubiquitin chain to securin and targets it for degradation by the 26S proteasome. The composition of APC has not been identified in plants, but we expect functional conservation with the 10 subunits of mammals and 13 subunits of yeasts. The APC activity also regulates cyclin degradation in mitosis. In plants, both the B-type and A-type cyclins can carry a short peptide motif of nine amino acids called the destruction (D)-box, which serves as a recognition site for APC. Reduction in the availability of cyclins could contribute to the loss of CDK activity at the end of mitosis. The APC function is under complex regulatory control, including an association with activator WD-repeat proteins such as Cdc20p (Fizzy) or Cdh1 (Fizzy-related) proteins that recruit substrates to APC. Components of the mitotic spindle checkpoint such as MAD (mitotic arrest deficient) and BUB (budding uninhibited by benomyl) proteins can inhibit APC activity. The APC is also regulated by cell cycle-specific phosphorylation; both kinases (Polo-like kinase, Plk1) and phosphatases (PP1) can activate APC.

After completion of mitosis, the phragmoplast serves as a scaffold to direct the movement of Golgi-derived vesicles containing cell wall components to form the new cell wall between the daughter nuclei. The phragmoplast complex is composed of two bundles of antiparallel MTs and actin filaments that are colocalized with number of kinesins. The process of phragmoplast expansion by reorganization from a solid cylinder into a ring-shaped structure is dependent on MT depolymerization in the center and reassembly-polymerization of MTs on the outside of phragmoplast. This lateral expansion of the phragmoplast can be arrested by brefeldin treatment, which prevents the establishment of a ring-shape and MT disassembly. Caffeine can disrupt cell-plate formation by interfering with the maturation of the fusion-generated vesicle membrane network into a wide tubular network in the phragmoplast. The cell plate grows outward by incorporating vesicles into the edge until it reaches the parental cell walls. The primary cell walls consist of cellulose, cellulose-binding hemicellulose, and pectins. Cellulose is generated at the plasma membrane in the form of paracrystalline microfibrils, whereas hemicellulose and pectins are synthesized within Golgi cisternae. After the formation of a new primary cell wall, the division procedure is complete and the separated daughter cells can either enter into a new division cycle or undergo differentiation.

**METAPHASE-TO-ANAPHASE TRANSITION AND CYTOKINESIS**

The release of cohensin-mediated chromosome cohesion at the metaphase plate is a prerequisite for the chromosome segregation in anaphase. The dissolution of cohesion between sister chromatids can be induced through degradation of cohensin by separases belonging to the
CONCLUSION

Our present knowledge about the major regulatory mechanisms of mitotic events is increased by the use of improved cytological techniques, based mainly on immunolocalization of key proteins. Detailed characterization of cell division mutants (primarily in Arabidopsis), and the cloning of the responsible genes provide essential functional information about control of the mitotic cell cycle. Overexpression of genes encoding proteins with roles in mitosis can be an alternative approach in functional analysis. In the future, detailed characterization of protein complexes and outlining cascades of phosphorylation/dephosphorylation during the perception of developmental or environmental signals will be needed. The DNA damage checkpoint will attract more attention. Discovery of the major controlling elements in endoreduplication is expected to highlight plant-specific elements in mitosis. Activity of meristems as major foci of mitotic events is under the precise control of a developmental program that can be altered by environmental influences.

Molecular Analysis of Chromosome Landmarks

James A. Birchler
Juan M. Vega
Akio Kato
University of Missouri, Columbia, Missouri, U.S.A.

INTRODUCTION

The major landmarks of a plant chromosome include the primary constriction, which represents the centromere; the ends of the chromosomes or telomeres; and blocks of heterochromatin, which, depending on the circumstances, can be rather discrete or diffuse. In many plant species a secondary constriction that represents the nucleolus organizer regions (NORs) is observed in one or more pairs of chromosomes. This secondary constriction encodes the major species of ribosomal RNA. The different landmarks consist of various types of repetitive sequences. This fact allows their molecular analysis to be facilitated by visualizing them using hybridization of probes to the mitotic metaphase or meiotic pachytene chromosomes.

CENTROMERES

The centromere is the structure present at the primary constriction of a chromosome. At this site, the proteins are organized in a complex called the kinetochore, which serves to move the chromosome to the poles at mitosis and meiosis. Moreover, at meiosis I, it serves to hold the two sister chromatids together during anaphase.

Among plant species, early molecular studies were of the B-specific repeat of the B chromosome centromere of maize and of the satellite repeat in Arabidopsis. The B-specific unit is approximately 1.4 kilobases in length and is only found in the centromere of the supernumerary B chromosome. Its location in the centromeric region was confirmed by analysis of B chromosome derivatives that have suffered from misdivision of the centromere. This process results when a centromere is present as a univalent in meiosis. The spindle attaches from both poles and ruptures the centromere transversely instead of separating it lengthwise. A number of misdivision derivatives have been studied and all change the restriction pattern identified by the B-specific repeat probe confirming the location of this unit within the B centromere.

The B centromeric repeat arrays extend over approximately 9 megabases in length. The misdivision derivatives reduce this size to as small as a few hundred kilobase pairs. Although other sequences are also included, the B-repeat cluster is likely to be throughout the centromere, based on the fact that misdivision can fracture this sequence and both fractured centromeres of the broken chromosome can still function.

The centromeric satellite sequence of Arabidopsis is 180 base pairs in length and is repeated many times at the site of the primary constriction of each of the five chromosomes of Arabidopsis. The length of the repeat cluster ranges from 1–2 megabases. The satellite cluster falls within the genetically defined centromere as determined by tetrad analysis.

For the A chromosomes of maize, there are other repeats present at the primary constriction of the respective chromosomes. One of the more prominent is the CentC unit (see Fig. 1). It is present at the primary constriction of all of the ten chromosome pairs to varying degrees. Another element, CentA, is present and variable as well. A third related element is CRM. The latter two repeats are retrotransposons that are specific in their location to the centromeric regions.

The centromeres of rice are also composed of a collection of repeats that are quite similar to those of maize. The satellite sequence referred to as CentO is a small repetitive element that contributes to slightly more than 1% of the rice genome. The representation of CentO in different centromeres of the twelve chromosomes is highly variable. Interspersed among the CentO repeats are copies of the CRR retroelement. Thus, a common feature of cereal centromeres is the presence of both conserved retrotransposons and species-specific tandem repetitive sequences. Functional centromeres are associated with a particular version of histone 3. A portion of the amino acid sequence of this histone is highly conserved relative to the normal version present in nucleosomes outside the centromere. However, one end of the molecule has
evolved very rapidly. To date, antibodies have been produced against the centromere histone 3 from Arabidopsis and from maize.\[9,11\]

NUCLEOLAR ORGANIZER REGIONS (NORS)

The ribosomal RNA genes are clustered by the hundreds or thousands of copies, often spanning millions of basepairs of chromosomal DNA at loci known as nucleolus organizer regions (NORs).\[12\] The number of NORs in a haploid chromosome set is characteristic of a species.\[13,14\] As a rule, at least one NOR is present per genome. During metaphase of mitosis, the NOR is usually observed as a secondary constriction on the chromosome. Upon exit from mitosis, transcription of the rRNA genes initiates the formation of a nucleolus. In interspecific hybrids, the NORs of one progenitor species are often inactivated, regardless of whether that species served as the maternal or paternal parent.\[15\] In this phenomenon, known as nucleolar dominance, silenced rRNA genes can be efficiently derepressed by chemical inhibitors of DNA methylation or histone deacetylation, implicating chromatin modifications in the maintenance of nucleolar dominance.

TELOMERES

The ends of chromosomes are capped by a specific sequence, called the telomere, which appears to stabilize the terminus. Typically broken chromosome ends will fuse with each other to generate chromosomal changes in structure. Alternatively, sister chromatids of a broken chromosome fuse at the ends after replication to initiate a bridge–breakage–fusion cycle. The addition of a telomere at the broken site will prevent such fusions.\[16,17\] Moreover, the presence of a telomere allows complete replication of the chromosome ends. Telomeres also cluster in meiosis before homologue synapsis.\[18\]

The first telomere sequence isolated from plants was from Arabidopsis.\[19\] The sequence is composed of the

---

Fig. 1  Fluorescent in situ hybridization of maize root tip metaphase chromosomes illustrating the locations of the centromeres (red) and the knob heterochromatic sites (yellow green). A probe for CentC was used to mark the centromeres. (View this art in color at www.dekker.com.)
repeat TTTAGGG in many tandem copies. Most plant species have the same structure.\textsuperscript{[20]} Adjacent to the telomere repeats are telomere-associated sequences that consist of degenerate versions of the repeats. Some few plant species, including members of Alliaceae and Aloe spp. (Asphodelaceae), were found to lack the Arabidopsis-type telomeric repeats.\textsuperscript{[21]}

Mutations in telomerase—the enzyme that synthesizes telomeric DNA—cause telomere shortening.\textsuperscript{[22]} This ultimately limits cell proliferation capacity because uncapped chromosome ends activate DNA damage checkpoints. Arabidopsis mutants that lack telomerase have unstable genomes, but manage to survive up to 10 generations with increasingly shortened telomeres and cytogenetic abnormalities.\textsuperscript{[22]}

\section*{HETEROCHROMATIN}

\subsection*{Pericentric Heterochromatin}

Most plant chromosomes have deeply staining heterochromatin surrounding the centromeres that displays gradual transition to more lightly staining regions called euchromatin. There are species, however—tomato being a prime example—in which the demarcation between centric heterochromatin and the euchromatin is very distinct. Typically there are few genes located in the pericentric regions and recombination values are low. Consequently the majority of genes are placed distally on the chromosome. The centric heterochromatin is likely composed of retrotransposon copies.\textsuperscript{[23]} In maize, some retroelements such as PREM\textsuperscript{[24]} are preferentially distributed around the centromeres.

\subsection*{Knob Heterochromatin}

Some plant chromosomes contain blocks of heterochromatin within the chromosome arms that are referred to as knobs.\textsuperscript{[1]} The most thoroughly studied knobs from the molecular point of view are those of maize (see Fig. 1). These chromosomal landmarks were first used as a means to distinguish the members of the maize karyotype in meiosis.\textsuperscript{[1]} Subsequently, they were found to act as neocentromeres and cause preferential segregation of linked markers through the female side.\textsuperscript{[25]}

This neocentric activity only occurs during meiosis. The knobs proceed to the poles ahead of the true centromeres. For preferential segregation to occur, heterozygosity is necessary for the presence or absence of a knob or at least for the size of knobs. A recombination event must occur between the true centromere and the knob to generate a heteromorphic dyad that pulls the knobbed chromatid to the outer poles during female meiosis. Because the most basal megaspore gives rise to the female gametophyte, the knob containing chromatid is recovered more often than random in the egg. The knobs act as neocentromeres only in the presence of an abnormal version of chromosome 10, which itself has a novel large knob near the end of the long arm.

Peacock et al.\textsuperscript{[26]} identified a repeat of 180 base pairs in length that is limited to knob heterochromatin. These units are arranged in tandem arrays interrupted by repetitive DNA sequences.\textsuperscript{[27]} Subsequently, another version was found (referred to as TR1) that is the major component of a few knobs.\textsuperscript{[27]} The neocentric activity in the knobs is not associated with the presence of the centromeric version of histone 3. Moreover, their attachment to the spindle is at an angle, in contrast to the perpendicular nature of spindle attachment to a normal centromere.\textsuperscript{[28]}

\subsection*{Constitutive Heterochromatin}

Constitutive heterochromatin refers to chromosome regions that remain condensed and transcriptionally inactive during interphase. They are enriched in tandemly repeated sequences of which the heterochromatic state is a heritable chromosomal trait. These regions include the already cited knobs and other heterochromatic blocks that reside in interstitial and terminal positions in many plant chromosomes. They can be visualized by conventional staining methods and a number of chromosomal banding techniques.

In plants, the first systematic analysis of the relationship between different heterochromatic bands and repetitive DNA sequences was done in rye.\textsuperscript{[29]} Several repeats arranged in tandem arrays, with repeating units of a few hundred base pairs, are located within the blocks of telomeric heterochromatin that can be observed on all seven pairs of rye chromosomes by C-banding. Most heterochromatic blocks contain more than one class of repeated elements. The size of the blocks varies among different rye accessions, indicating that the copy number of the DNA sequences may change extensively.

The heterochromatic state is highly stable. However, an interstitial C-band present in rye 5R chromosome is unusually decondensed when this chromosome is added to wheat. In the wheat background, this region appears as a constriction, which coorients with the true centromere and shows neocentric activity at meiosis.\textsuperscript{[30]} This phenomenon resembles the situation observed with maize knobs. However, whereas maize neocentromeres interact with spindle microtubules in a lateral manner, the 5R neocentromere shows end-on contact with microtubules, in a way similar to the binding of true centromeres. Tandem arrays...
of a 118 base pair monomeric unit are present at the 5R neocentromere.

CONCLUSION

The major landmarks of plant chromosomes are typically composed of repeated units of one type or another. The telomeres are synthesized by an enzyme (telomerase) that adds the appropriate sequence to the ends of the chromosomes. The basis for the maintenance of the centromeric repeats, especially considering their uniformity on nonhomologous chromosomes, is unknown. Also unknown are the exact sequence requirements to specify a centromere. Because the putative cis-acting centromeric sequences are not conserved, even in closely related species, it is possible that centromeric identity is not determined by DNA sequence but rather by chromatin assembly during replication. The accumulation of some repeated sequences under these sites might be unrelated to the specification of the centromere location. Future work is needed to reveal the nature of the centromere determination.

Molecular Biology Applied to Weed Science

Patrick J. Tranel
Federico Trucco
University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

Weed science is a very practical discipline that has the general goal of improving weed management. To achieve this goal, however, weed scientists historically have relied on many basic scientific disciplines, such as plant physiology, biochemistry, chemistry, and genetics. In recent years, the tools afforded by molecular biology techniques also have been brought to weed science. In fact, among the first and most widely adopted outcomes of biotechnology were weed science products, namely herbicide-resistant crops. Molecular biology tools are also being widely used in weed science to investigate fundamental questions regarding the biology, ecology, and evolution of weeds. The application of molecular biology tools to weed science is described and illustrated with several examples.

RECENT EVENTS IN THE HISTORY OF WEED SCIENCE

Although humans have contended with weeds for millennia, rapid growth of weed science as a discipline did not occur until the middle of the 20th century, after the discovery of the first synthetic herbicides. Throughout much of the latter half of the 1900s, weed science was focused on herbicide discovery and herbicide physiology. Weed scientists were tremendously successful, increasing the efficacy and range of new herbicidal chemistries and thereby simplifying and improving weed management. As a result, soil conservation practices expanded and yields improved. Herbicides also aided basic biological research. For example, much of what we now know about the shikimic acid pathway (which is disrupted by the herbicide glyphosate) and photosynthetic electron transport (disrupted by triazine and other herbicides) was discovered by weed scientists investigating herbicide phytotoxicity.

Herbicide-Resistant Weeds

A repercussion of the wide adoption of herbicides for weed management was the evolution of herbicide-resistant weed populations. This phenomenon continues to be an area of intense weed science research, and is greatly aided by molecular biology. Illustrative of this point are investigations of resistance to herbicides that inhibit the enzyme, acetolactate synthase (ALS).

The ALS enzyme is necessary for the production of certain amino acids, so inhibition of this enzyme leads to plant death. Numerous herbicides, most of which belong to either the sulfonylurea or imidazolinone chemical group, target this enzyme and have been widely used since the early 1980s. Although these herbicides have been very effective, populations of more than 70 weed species have evolved resistance to these herbicides. In most cases in which it has been investigated, resistance was determined to be due to an altered target site. More specifically, mutations in the gene encoding ALS result in the production of herbicide-insensitive versions of the ALS enzyme. Multiple mutations have now been identified from resistant weed populations and are being catalogued. Identification of these mutations and the corresponding patterns of resistance to the various ALS-inhibiting herbicides has greatly improved our understanding of how these herbicides interact with their target site.

Herbicide-Resistant Crops

In recent years, application of molecular biology research methods to herbicide physiology and herbicide resistance in weeds has furthered our understanding in these areas. Taking this idea a step further, our understanding of herbicide phytotoxicity at the molecular level has enabled the most recent revolution in weed science: the development and commercialization of herbicide-resistant crops.

Herbicide-resistant crops are perhaps the most consequential outcome of molecular biology applied to weed science. Among these, glyphosate resistance technology stands as the best example. Glyphosate’s ability to control a broad spectrum of weeds, its low toxicity to humans and other nontarget organisms, and its limited environmental persistence have made it a good candidate for efforts at engineering herbicide-resistant crops.

Glyphosate targets the enzyme 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS). First attempts to
engineer glyphosate resistance involved overexpression of the gene encoding EPSPS and expression of mutated forms of the gene encoding glyphosate-insensitive variants of the enzyme.\[^3\] Although marginally successful, such attempts did not result in commercially acceptable levels of glyphosate resistance. The screening of microorganisms resulted in identification of a second type of EPSPS enzyme (Class II EPSPS) that was highly resistant to glyphosate. A Class II EPSPS gene was cloned from Agrobacterium spp. strain CP4 and expressed in crop plants. Success in using the CP4 EPSPS gene led to the commercialization of glyphosate-resistant soybean in the United States in 1995, followed by canola and cotton in 1997 and corn in 1998.\[^4\] Since 1996, the worldwide adoption of glyphosate-resistant crops has been immense (Fig. 1).

Transgenic approaches also have been used to obtain other commercial forms of herbicide-resistant crops. Additionally, mutagenesis has been used with success in nontransgenic attempts to obtain herbicide resistance. In this approach, resistant variants are selected from a population of the crop of interest. To improve the chance for success, genetic variation in the population is increased by using one of several techniques to induce mutations in the plants.

Regardless of the specific technique used, the development of herbicide-resistant crops has increased options for weed management, and several such crops are now commercially available (Table 1). Although often criticized by environmental groups, such crops—if used wisely—offer great promise for reducing detrimental impacts of weeds and for developing more sustainable weed management systems.

### MOLECULAR BIOLOGY APPLIED TO THE BIOLOGY, ECOLOGY, AND GENETICS OF WEEDS

Weed scientists have often wondered what the underlying mechanisms are that contribute to the success of weeds. Tools of molecular biology offer novel ways of approaching this question.

#### Tools to Study Genetic Diversity

It is often hypothesized that large genetic diversity in weed species allows them to survive and adapt to changing agroecosystems. In the past, phenotypic markers were used to measure such diversity. However, because such markers may be influenced by environmental conditions, they do not always reflect genetic diversity. Molecular markers are a significant improvement for the study of genetic diversity.\[^5\]

The first widely used molecular marker system used isozymes. Different versions of a particular enzyme can be separated by electrophoresis, due to different migration rates, and thus can provide a scoreable genetic marker. The discovery of restriction endonucleases (enzymes that cleave DNA) led to development of DNA markers based on restriction fragment length polymorphisms (RFLPs). The RFLP system detects genetic diversity based on the presence or absence of specific nucleotide sequences that are recognized by the restriction endonucleases.

Development of polymerase chain reaction (PCR) technology led to the improvement of DNA-based molecular markers into finer-scale genetic assessment techniques, such as amplified fragment length polymorphism (AFLP) and random amplified polymorphic DNA (RAPD). In general, AFLPs are based on the same principles as RFLPs, but with enhanced resolution provided by PCR amplification. RAPD markers rely on random amplification.

![Fig. 1  Glyphosate-resistant soybean hectares as a percentage of total soybean hectares. The United States, Argentina, and Brazil produce 90% of the world’s soybean exports. Note the high adoption in Brazil, despite the fact that glyphosate-resistant soybean is not legal in that country. (From http://soystats.com, accessed March 2003.)](image-url)
of DNA by means of short, arbitrary primers. Other variants of these PCR-based techniques have been used to target extremely diverse regions of genomes constituted by tandemly repeated sequences. Genetic diversity can be examined at the finest possible level by comparing nucleotide sequence information (i.e., by direct DNA sequencing).

**Application of Genetic Diversity Tools: Studying Gene Flow**

Studies that explore the mechanisms by which genetic diversity is acquired gained new force with the use of molecular biology tools. In particular, molecular biology has been invaluable in research examining gene flow among populations of the same species and between different species. Interspecific gene flow has been studied between some crops and their weedy relatives and among weed species themselves.[6] In most cases, gene flow has been studied in the context of herbicide resistance transmission. Hybrid intermediates between herbicide-susceptible and herbicide-resistant populations have been detected using a variety of molecular techniques. Such studies have made it possible to understand the significance of gene flow in the evolution of weed species. Furthermore, such studies are instrumental in predicting the risk that a herbicide-resistant crop may outcross with a weedy relative.

**Gene Expression Profiling**

Molecular biology can greatly facilitate understanding of how weeds respond to their environment, whether it be growing in competition with crops, surviving herbicide treatment, or initiating flowering after an early frost. In particular, a variety of techniques that can be loosely grouped in a category called gene expression profiling are ideally suited for such studies. The aim of gene expression profiling is to determine what genes are “turned on” or “turned off” in response to a particular treatment or environment. Results from such studies could provide insight at the molecular level as to how a weed responds to a particular treatment.

Modern gene expression profiling techniques (e.g., DNA microarrays) allow monitoring of thousands of genes simultaneously.[7] Such so-called “genomics” analyses have been adopted recently with model organisms—including plants such as Arabidopsis and several crop species—but have seen scant use in weed science research. As this technology becomes more commonplace, it likely will be applied to several aspects of weed science. Basic questions regarding biological phenomena important to weediness, such as induction of flowering, seed dormancy, and control of vegetative reproduction could be readily addressed with genomic techniques.

**CONCLUSION**

As illustrated by the foregoing examples, molecular biology research techniques provide many opportunities for advancements in weed science. In the future, molecular approaches will continue to provide new tools for managing weeds and will provide new information about the weeds themselves.

INTRODUCTION

The field of molecular evolution combines the tools of chemistry and molecular biology with the theoretical constructs of population genetics and systematics. It borrows concepts and methods from many areas of science—including mathematics, statistics, computer science, systematics, molecular biology, genetics, and chemistry—in addressing questions about the evolution of molecules and the evolution of the organisms that possess and transmit those molecules. Molecular evolution has both static and dynamic dimensions, ranging from the study of phylogeny to the experimental investigation of novel catalytic RNA molecules in test-tube environments. Molecular evolution is a comparative science in which inferences are made from the analysis of molecular data sampled from different organisms or from different gene copies within a genome. At its broadest, the science of molecular evolution can be defined as the study of the processes that cause molecular change and the application of that knowledge to our understanding of the history of life on Earth.

The goal of this article is to provide a brief overview of the current state of knowledge of plant molecular evolution. It will also discuss several exemplar problems relevant to crop evolution. A number of excellent books have been published in recent years that provide a detailed treatment of various aspects of molecular evolution, and these should be consulted by readers who wish to study molecular evolution in greater depth.

PLANT GENOMES AND THEIR EVOLUTIONARY PATTERNS

Plants possess three genomes: a chloroplast genome (denoted cpDNA), a mitochondrial genome (denoted mtDNA), and a nuclear genome (denoted nDNA). Each of these genomes has different origins and different evolutionary dynamics. A few of the most important features of the evolution of these genomes will be described briefly in the following sections.

HOW THE ANCESTORS OF PLANTS LEARNED TO CAPTURE ENERGY THROUGH PHOTOSYNTHESIS

A number of convergent lines of evidence provide overwhelming support for the hypothesis that the cpDNA genome originated from an endosymbiotic association between a cyanobacterialike photosynthetic organism (a prokaryote) and an eukaryotic cell. Thus a prokaryote donated the capacity for photosynthesis to the eukaryotic lineage that ultimately evolved into algae and land plants. As the endosymbiotic association evolved it became an obligate relationship, and many genes were transferred from the prokaryotic genome of the endosymbiont to the genome of the eukaryotic host. This transfer process probably occurred over hundreds of millions of years and may still be ongoing. It represents one of the clearest and most massive cases of horizontal gene transfer in plant evolution. Phylogenetic analysis provides one of the most important lines of evidence for gene transfer, because it reveals that many nuclear-encoded components of photosynthesis are most closely related to cyanobacterial genes with the same (homologous) function.

The cpDNA molecule was the first genome to be studied in plant molecular biology and evolution because it was relatively easy to purify and it encoded a limited number of base pairs (bp) in size and includes approximately 80 protein coding genes; 30 to 32 tRNA genes; and operons encoding the 16S, 23S, and 4.5S ribosomal RNA genes. This inventory reveals that the chloroplast has its own protein synthesizing machinery. However, many of the functional components of photosynthesis are nuclear-encoded, owing to the prior history of gene transfer to the nuclear genome, and these polypeptides must be imported into the chloroplast for photosynthetic competence. There is considerable evidence of gene transfer from the cpDNA into both nDNA and mtDNA, but evidence for gene transfer into the cpDNA is essentially absent.

The cpDNA molecule was the first genome to be studied in plant molecular biology and evolution because it was relatively easy to purify and it encoded a limited number of base pairs, thus facilitating molecular cloning and analysis. An important early discovery was a rate of
Molecular Evolution

Evolution for proteins encoded on the cpDNA molecule about five times slower than is typical for plant nuclear protein-coding genes. The significance of the conservative (slower) rate of evolution is that it allows the alignment and analysis of gene sequences that span much greater periods of evolutionary time. This discovery led to a major effort to construct land plant phylogenies based on cpDNA genes. The gene initially selected for this effort was rbcL. The rbcL gene encodes the large subunit of the enzyme ribulose-1, 5-bisphosphate carboxylase that fixes CO2 in the carbon cycle. rbcL was the first cpDNA protein-coding gene to be cloned and sequenced, and thus it was a natural candidate for these early efforts. To date more than 2500 rbcL sequences are available from land plants, and these data provide an unprecedented picture of land plant phylogeny. An entire field of plant molecular systematics has grown up around the use of cpDNA (and more recently certain nuclear genes) to infer plant phylogenetic history.

**ORIGINS OF THE PLANT MITOCHONDRIAL GENOME**

The plant mitochondrial genome also owes its origins to an early endosymbiotic association. In this case the enzymatic machinery for oxidative phosphorylation was donated to the eukaryotic lineage by an α-proteobacterial (prokaryotic) source prior to the separation of plant and animal lineages. Thus the evolutionary origins of the machinery that permitted the eukaryotic lineage to utilize oxygen and to adapt to an increasing partial pressure of oxygen in the atmosphere were also the result of a prokaryotic association. Many lines of evidence, including phylogenetic analysis, support this conclusion.

The plant mitochondrial genome reveals a strikingly different pattern of evolution when compared to either the chloroplast genome or animal mtDNA. First, the plant mtDNA exhibits a least a tenfold range in total DNA content (from 200,000 bp to 2,000,000 bp). Second, plant mtDNA appears to acquire and integrate DNA fragments from both cpDNA and nDNA sources, and this is thought to account for the large size variations. Third, plant mtDNA shows very high frequencies of genomic rearrangements, in contrast to remarkable stability for cpDNA. Fourth, protein-coding genes on the plant mtDNA are among the slowest-evolving genes characterized to date (roughly ten times slower than nDNA protein-coding genes). Fifth, the frequent loss of certain classes of genes from mtDNA is apparent over flowering plant evolution. And sixth, the mtDNA has repeatedly been invaded by a mobile element (group I intron) that appears to derive from a fungal source, providing clear documentation of horizontal gene transfer in recent evolutionary time.

An important digression: It is remarkable that two of the major biochemical adaptations—photosynthesis and oxidative phosphorylation—that allowed eukaryotes to become dominant life forms on the terrestrial earth were acquired through endosymbiotic associations that each involved massive horizontal gene transfer to the eukaryotic nuclear genome. This history illustrates an important fact about evolution. Evolution is modular and occurs at several hierarchical levels. Molecular evolution is not simply the process of nucleotide substitution or the accumulation of individual amino acid substitutions in proteins over time. It is an open-ended process where genetic change can and does occur at all levels of organismal complexity. The analytical tools for studying the regular processes of nucleotide change allow us to infer time and to reconstruct history, albeit imperfectly. Inferences based on these tools tell us a rich story about the complexity of biological evolution. Perhaps the most important lesson is the hierarchical nature of genetic change.

**EVOLUTION OF THE PLANT NUCLEAR GENOME**

The eukaryotic nuclear genome is a mosaic of different histories. We have already seen that prokaryotic genes from both cyanobacterial and α-proteobacterial sources have been incorporated into nDNA. Very early in organismic evolution an association between eubacterial and archaebacterial cells appears to have arisen as an adaptation to oxygen poisoning. The eubacterium was motile and could avoid high oxygen concentrations while the archaebacterium provided an energy source in the form of sulfide. Ultimately the two genomes fused, and the nuclear envelope compartmentalized the integrated genome. So once again we are reminded of the great plasticity of genetic evolution in leading to novel life forms.

We are beginning to acquire a detailed picture of the genetic complexity of the plant nuclear genome as a result of the recent sequencing of the *Arabidopsis* genome. Moreover, a public version of the rice genome is now available. The ability to compare monocot (rice) and dicot (*Arabidopsis*) genomes should tell us much about the elaboration of gene function in the roughly 150 million years of angiosperm evolution. At the time of this writing our most comprehensive knowledge derives from analyses of the *Arabidopsis* genome sequence. A number of important facts have emerged from this project. First, many plant genes are present in multiple copies as a result of duplication over evolutionary time. Some of these gene
families have diversified and expanded so that they contain in excess of one hundred gene duplicates, as discussed below. Second, gene-rich and gene-poor regions characterize the chromosomes of *Arabidopsis*, so the distribution of coding information appears to be heterogeneous across plant genomes. Third, transposable elements are a ubiquitous feature of plant genomes.

**Evolution of Plant Gene Families**

Multiple related genes (gene families) encode many important metabolic and regulatory functions. Gene families originate through gene duplication and subsequent divergence in function or in developmental expression. An example of a gene family that encodes an enzyme important in plant secondary metabolism is chalcone synthase (CHS). The CHS enzyme catalyzes a condensation reaction that yields a 15-carbon three-ring structure that is the first committed step in flavonoid metabolism. The CHS gene family exists in multiple copies in most plant genomes studied to date. For example, in plants of the morning glory genus (*Ipomoea*) there are at least six copies. It is possible to study the evolution of these genes using the computational tools of bioinformatics, and these analyses reveal two distinct subfamilies that duplicated and diverged from one another very early in flowering plant evolution. One subfamily (comprising genes *chs* D and E) performs the chalcone condensation reaction, but the two genes have diverged in tissues-specific patterns of expression.\(^{[10]}\) The second subfamily (comprising genes *chs* A, B, C and a pseudogene) appears to have evolved a new catalytic function. This illustrates the fact that duplicate genes can provide a substrate for adaptive divergence by providing new developmental or metabolic capabilities to the plant.

The MYB family of transcriptional activators provides a second example that illustrates the very high levels of redundancy achieved by some plant gene families. MYB proteins are involved in DNA binding by a helix-turn-helix configuration. All known MYB proteins—including those found in plants and animals—have common structural features defined as the R1, R2, and R3 subdomains that are essential for the DNA binding function. The redundancy of MYB genes in plant genomes is much higher than observed in animal genomes. There appears to have been a proliferation of these genes that began early in land plant evolution so that more than 100 duplicate copies of MYB genes are found in the *Arabidopsis* genome. Analyses of the molecular evolution of this gene family reveal at least eight cases where rates of protein evolution accelerated following duplication events, as indicated by excess rates of amino acid change compared to synonymous change, suggesting positive selection at the protein level. Moreover, it is possible to identify specific nucleotide sites where presumably adaptive amino acid substitutions have occurred. It appears that this family of transcriptional activators has proliferated through duplication and evolved through nucleotide substitution to meet a wide array of regulatory needs within plant genomes. The computational methods of molecular evolution provide a powerful approach to the identification of the precise amino acid changes that are adaptive.

**APPLICATIONS IN THE STUDY OF PLANT EVOLUTION AND CROP IMPROVEMENT**

**Studies of Molecular Diversity**

Application of the coalescent framework to samples of nucleotide sequence data are important in

- Screening loci for evidence of past selection
- Determining effective population sizes
- Evaluating general levels of genetic diversity
- Designing germplasm conservation programs
- Tracing the genetic correlates of crop domestication

A second question of importance concerns the structure of molecular diversity. In particular, it is of considerable practical utility to measure the effectiveness of recombination in randomizing different nucleotide sites on a chromosome as a function of physical or genetic distance. Put a different way, it is important to estimate a quantity known as linkage disequilibrium (LD) that measures the correlation in nucleotide state among pairs of nucleotide sites. This follows because correlations within or among genes may act to retard the operation of selection and thereby slow plant breeding progress. To see this, imagine a deleterious gene that is correlated in transmission with a selectively favored gene. The net effect, obviously is, to retard the increase of the favored gene or to slow the elimination of the deleterious gene. Finally, there is substantial contemporary interest in using single nucleotide polymorphisms (SNPs) as a tool for the genetic mapping of useful traits and for marker-assisted selection. This application requires that the marker SNP be correlated in transmission with the actual gene of interest.

There is a small but growing body of data on nucleotide sequence diversity in plants, most of which derives from the model plant *Arabidopsis*, although data increasingly are becoming available from crop plants such as maize and barley. Both *Arabidopsis* and barley are predominantly self-fertilizing plants, and population genetic theory predicts reduced levels of variation in inbreeding...
plant species. Moreover, population genetic theory predicts high LD in inbreeding species. Both of these predictions follow from the fact that self-fertilization reduces heterozygosity by a factor of 50% per generation. A population is expected to be composed of a collection of homozygous lines very quickly. Effective recombination occurs only in heterozygotes, so inbreeding greatly reduces the effective rate of recombination—and this should promote higher levels of LD. The effective population size of self-fertilizing populations is half that of comparable random-mating populations, and selection is more effective among homozygous lines. Accordingly, we expect reduced levels of genetic diversity in self-fertilizing species. Current data are equivocal with regard to these two predictions. Levels of LD in Arabidopsis are high, but not as high as might be expected relative to, say, human populations.\textsuperscript{11} Preliminary evidence from barley also indicates only modest increases in LD relative to maize.\textsuperscript{12} Levels of genetic diversity are reduced in inbreeding species, and this generalization is well supported by massive isozyme data analyses.\textsuperscript{13} Nevertheless, most self-fertilizing species possess considerable stores of genetic variation and numerous experiments show that self-fertilizing species are able to respond to selection on virtually any phenotypic character.\textsuperscript{14}

**Plant Relationships and Crop Origins**

Molecular data are providing important insights into crop plant domestication. This topic is dealt with at greater length in other sections of this volume and will only be touched on here. One place where markers are especially helpful is unraveling the complex network of relationships associated with hybridization in plant domestication. To cite a single example, the cultivated avocado is a genetically diverse assemblage comprising three botanical varieties. Microsatellite markers provide a means of identifying the genetic origins of various cultivars, because many loci can be screened to provide an informative average picture of the genomic history of particular lineages. Work of this kind shows clearly that many popular cultivars are the result of intervarietal hybridization. In the longer term this kind of work should also provide clear evidence regarding the geographic origin of useful materials, and it should provide a helpful guide for genetic conservation.

**CONCLUSION**

Molecular evolutionary analyses have provided a rich picture of the evolution of plant genomes. This picture begins with the very early endosymbiotic events that presumably led to the eukaryotic cell and continues to the later acquisition of the machinery for photosynthesis and oxidative phosphorylation. Along the way, gene redundancy is seen to have played a major role in the elaboration of biochemical and developmental novelty. An important lesson is thus gleaned: the recognition that molecular evolution has proceeded at several levels, including the level of protein evolution through nucleotide and amino acid substitution, the level of gene duplication, and the level of whole genome transfer events that have taken place several times in the long course of evolution.

INTRODUCTION

The large-scale production of recombinant proteins in plants is known as molecular farming. Plants have many advantages in terms of cost, practicality, and safety over traditional expression systems and are emerging as a significant force in the commercial sector. Providing adequate yields can be obtained, it is estimated that recombinant proteins can be produced in plants at 2–10% of the cost of microbial fermentation systems and at 0.1% of the cost of mammalian cell cultures/transgenic animals. Plants lack the endotoxins often produced by microbial cultures and, unlike animal cells, do not harbor human pathogens or oncogenic DNA sequences. Posttranslational modification occurs in a similar manner in plant and animal cells with only minor differences in glycan chain structure, which makes plants suitable for the production of complex human glycoproteins. Plants also have a number of unique practical advantages such as the high stability of proteins expressed in seeds and the ability to express pharmaceutical proteins in edible organs for oral administration with minimal processing.

PLANT-BASED EXPRESSION SYSTEMS

Transgenic Plants

In the vast majority of cases, molecular farming has been achieved by stable transformation and the regeneration of transgenic plants. Several crop species have been used as expression hosts, and the best choice for any particular protein must be determined on an empirical basis according to intrinsic properties of the plant (Table 1) and economic factors. This might include the value and intended use of the recombinant protein and the local availability of labor, storage facilities, processing, and distribution infrastructure.

Tobacco has the longest history as a successful expression system for molecular farming and is one of the best candidates for the commercial production of recombinant proteins. The advantages of tobacco include the well-established technology for gene transfer and expression, the high biomass yield (over 100,000 kg per hectare for close-cropped tobacco), and the existence of large-scale infrastructure for processing. However, a major disadvantage of leafy crops is protein instability. The leaf tissue must be frozen or dried for transport or processed at the harvesting site. In contrast, seed-based expression allows long-term storage at ambient temperatures because the proteins accumulate in a stable form. Several different crops have been investigated for seed-based production, including the cereals rice, maize, and wheat. Prodigene Inc. chose to use maize for the first commercial molecular farming venture due to the combination of high biomass yield and the ease of in vitro manipulation; three technical proteins have been marketed successfully. Recombinant proteins have also been produced in fruit and vegetable crops, which are beneficial because the products can be expressed in edible organs for oral administration. Clinical trials have been carried out using vaccine candidates, antibodies, and enzymes expressed in leafy crops, seeds, and vegetables, and several companies have plant-derived pharmaceuticals in the late stages of clinical development.

Transgenic plants are the most cost-effective platform in molecular farming because crops can be established, maintained, harvested, and processed using traditional agricultural practices and existing infrastructure. However, a development phase of 18 months to two years is required to produce the first generation of transforms, and biosafety concerns that transgenes and their
products could spread in the environment are limiting public acceptance.\(^6\) This has prompted research into alternative plant-based technologies for recombinant protein production.

### Transplastomic Plants

Chloroplast transformation is a useful alternative to nuclear transformation in molecular farming applications because there are many chloroplasts in the cell, resulting in a high transgene copy number in the transplastomic plants. This, together with the fact that chloroplast transgenes appear not to suffer from position effects or epigenetic transgene silencing, produces unprecedented levels of recombinant protein, in the best cases reaching nearly 50% total soluble protein.\(^7\) Disulfide bonds are formed correctly in chloroplast-derived recombinant proteins, but there is no glycosylation. In biosafety terms, transplastomic plants are advantageous because there are no plastids in the pollen grains of most crops, thus limiting gene flow by pollen dispersal. Chlorogen, Inc. was established in 2003 to commercialize the chloroplast transgenic system.

### Transient Expression Systems

Transient expression assays are often used to evaluate the activity of expression constructs or test the functionality of recombinant proteins, but they can also be used as a routine molecular farming platform if moderate amounts of protein can be produced.\(^8\) This is possible using the agroinfiltration method, where recombinant *Agrobacterium tumefaciens* are infiltrated into tobacco leaf tissue and milligrams of protein can be produced within a few weeks.\(^9\) The advantages of agroinfiltration include the minimal set-up costs and the rapid onset of protein expression, but scaling up is neither as economical nor as convenient as is the case with stably transformed plants.

### Virus-Infected Plants

In addition to *Agrobacterium*-mediated transformation and direct DNA transfer, plant viruses can also be used as vectors to deliver foreign genes into plants.\(^10\) Although viral gene transfer does not result in stable transformation, the prolific replication and systemic spread of many plant viruses means that the onset of recombinant protein expression is rapid and the total yield is high, two features that are ideal for molecular farming. Thus far, viral vectors have not been widely used for molecular farming, perhaps because there is a limit to the amount of DNA that can be incorporated into such constructs. Tobacco mosaic virus (TMV) and potato virus X (PVX) vectors have both been used for the production of recombinant antibodies in tobacco, including scFv fragments and a full-sized IgG. In the latter case, two different TMV vectors containing the heavy and light immunoglobulin chain genes, respectively, were used to coinfect the plant, and correct assembly of the protein occurred in planta.

### Plant Cell Suspension Cultures

The production of recombinant proteins in plant cell suspension cultures is an alternative approach that may be beneficial where defined and sterile production conditions and high-level containment are required, e.g., for the production of pharmaceuticals.\(^11\) Plant cell suspensions are normally derived from callus tissue that has been

OPTIMIZING PRODUCTION OF ACTIVE RECOMBINANT PROTEINS

Maximizing the Rate of Transcription and Translation

The production of active recombinant proteins in plants can be optimized at each stage of gene expression.\[13\] Generally, it is useful to use a strong and constitutive promoter to maximize the rate of transcription. The cauliflower mosaic virus 35S RNA promoter (CaMV 35S) is widely used in dicots, while the maize ubiquitin-1 promoter (abi-1) is preferred in monocots. However, there are also advantages to the use of tissue-specific and inducible promoters. The use of seed-specific promoters, for example, prevents the accumulation of recombinant proteins in vegetative organs. This limits toxicity effects in the host plant and reduces the likelihood that herbivores and other non-target organisms will be exposed to the protein. Similarly, inducible promoters activated by chemicals such as tetracycline or by mechanical stimuli can be used to initiate protein accumulation prior to or even after harvest.

The rate of protein synthesis can be optimized by eliminating native 5’ and 3’ untranslated regions from the foreign gene and replacing these with elements that increase mRNA stability and enhance translational efficiency, such as the 5’ leader sequence of the tobacco mosaic virus RNA (the omega sequence). It is also useful to change the translational start site of the expression construct to conform to the Kozak consensus for plants. For some transgenes, it may be necessary to modify the coding region to match the codon usage preferences of the expression host.

Protein Targeting and Modification

Subcellular targeting influences protein stability (thus affecting the yield), determines the type of modification that takes place (thus affecting protein structure and activity), and can be exploited to simplify downstream processing (e.g., by including affinity tags or fusions). Targeting to the secretory pathway is beneficial, especially if the protein is normally glycosylated since this modification takes place in the endoplasmic reticulum (ER) and Golgi apparatus. The environment of the ER also promotes correct protein folding and thus increases stability. This has been demonstrated in the case of recombinant antibodies, which accumulate in the secretory pathway at levels up to 100-fold greater than in the cytosol.\[14\] Targeting to the secretory pathway is achieved by incorporating an N-terminal signal sequence into the expression construct that directs the ribosome to signal receptors on the endoplasmic reticulum. The default destination of proteins targeted to the secretory pathway in plants is the apoplastic space under the cell wall, where they may be retained or secreted depending on their size. Still higher protein levels can be achieved by adding a C-terminal H/KDEL sequence, which causes the recombinant protein to be retrieved from the Golgi and returned to the ER lumen, in the manner of a resident ER protein.\[15\]

CONCLUSION

Plants have practical and economical advantages over traditional expression systems, making them suitable for the large-scale production of recombinant proteins. Technological issues that remain to be addressed include the optimization of yields, the modification of glycan structures, and improved biosafety. In order to be commercially viable, plants must produce a target protein at a level exceeding 1% total soluble protein. This has been possible for many proteins, but some unstable proteins tend to accumulate at a level of 0.01–0.1%, often reflecting incorrect folding, assembly, or degradation during extraction. Biosafety issues remain at the forefront of current molecular farming research. Such issues include the development of novel ways to prevent transgene spread, to restrict unnecessary exposure of non-target animals and microbes to transgenes and their products, and to prevent transgenic plant material mixing with the food and feed chains.

Molecular Integrated Cytogenetic Mapping

Jiming Jiang
University of Wisconsin-Madison, Madison, Wisconsin, U.S.A.

INTRODUCTION

Traditional cytogenetic mapping relied on aneuploids, which are often difficult to develop and maintain. Common wheat (Triticum aestivum, 2n = 6x = 42) has long been the classical model for cytogenetic mapping mainly because of its amenability to aneuploidy. Another critical component of cytogenetic mapping is the identification of individual chromosomes in a plant species. Unfortunately, identification of individual chromosomes was impossible in the majority, if not all, of plant species before the modern chromosome banding and DNA in situ hybridization techniques became available. Therefore traditional cytogenetic mapping went through a technically difficult stage with slow progress. The development of molecular marker technologies and fluorescence in situ hybridization (FISH) techniques have dramatically enhanced the power and efficiency of cytogenetic mapping. Because of these new techniques, aneuploids and other cytogenetic stocks can also be more effectively used in cytogenetic mapping.

CHROMOSOME IDENTIFICATION USING MOLECULAR CYTOGENETIC DNA MARKERS

Cytogenetic mapping requires reliable and easy-to-use techniques for chromosome identification. Unfortunately, chromosome identification is a major challenge in many plant species, especially those with large numbers of small chromosomes. Meiotic pachytene chromosomes are significantly longer and provide more cytological features than somatic metaphase chromosomes for chromosome identification. Cytogenetic mapping based on pachytene chromosomes was especially successful in maize,[1] tomato,[2] and rice.[3] However, pachytene chromosome preparation can only be applied in species with relatively few and small chromosomes. Chromosome identification based on banding analysis has been reported in many plant species. However, the banding techniques are practically useful and can only be routinely used in cytogenetic mapping of few plant species. The most versatile and promising new chromosome identification technique is the application of chromosome-specific cytogenetic DNA markers (CSCDMs).[4] This methodology identifies chromosomes based on hybridization signals derived from DNA markers that are specific to individual chromosomes in a plant species. CSCDMs can be isolated by screening large-insert genomic DNA libraries with DNA probes that have been mapped to individual linkage groups. CSCDMs were successfully developed in potato and sorghum by screening bacterial artificial chromosome (BAC) libraries.[4,5] Additionally, repetitive DNA elements that hybridize to one or few chromosomes can also be used as CSCDMs.[6,7]

The CSCDM-based chromosome identification system has several advantages compared to the traditional pachytene and banding analyses. First, this method is straightforward and each chromosome can be readily distinguished from the rest of the chromosome complement, while it is difficult to distinguish chromosomes with a similar morphology or banding pattern by pachytene or banding analysis. Thus the CSCDM-based approach is particularly effective for analyzing the mitotic and meiotic behavior of a particular chromosome.[6] Second, the quality of the chromosome preparations is not important for chromosome identification using CSCDMs, while the quality of chromosome spreads is critical to the success of banding and pachytene chromosome analysis. Third, the CSCDM-based approach can be applied in any plant species with small or large chromosomes. Pachytene analysis and chromosome-banding techniques can be used only in certain plant species. Fourth, the chromosome identified by a CSCDM can be correlated directly with a specific linkage group.

CYTOGENETIC MAPPING USING FISH

FISH has become the most popular technique to map DNA sequences directly onto plant chromosomes.[8,9] Compared to other physical mapping techniques, FISH is a quick and relatively affordable approach. FISH can be applied to a variety of cytological targets. Commonly used cytological targets for FISH mapping include mitotic metaphase chromosomes, meiotic pachytene chromosomes, and extended DNA fibers.

Somatic metaphase chromosomes are the most popular cytological targets for FISH mapping mainly because mitotic tissues are readily available and mitotic
chromosomes are relatively easy to prepare. However, the highly condensed metaphase or prometaphase chromosomes are difficult to distinguish and provide a low resolution for the purposes of mapping. Pedersen and Linde-Laursen[10] suggested that a minimum of 5–10 Mb would be necessary to resolve DNA clones on barley metaphase chromosomes. Cheng et al.[11] recently demonstrated that at prometaphase, the majority of the signals derived from two BAC clones separated by less than 1 Mb overlapped completely on the distal euchromatic region on the long arm of rice chromosome 10. It was suggested that the minimum physical distance required to resolve two DNA clones will be substantially larger than 1 Mb in the proximal regions of prometaphase chromosomes and in the more condensed metaphase chromosomes.[11] Despite its low resolution, the mitotic metaphase chromosome-based FISH mapping is an easy and quick approach to determine the chromosomal location of targeted DNA probes.

The meiotic pachytene chromosomes are usually 10–20 times longer than somatic metaphase chromosomes. Thus the highly extended pachytene chromosomes provide a superior resolution for FISH mapping. The resolution of pachytene FISH depends on early or late stages of individual pachyteny cells, as well as the locations of the targeted DNA clones in the heterochromatic or euchromatic regions.[9,11,12] In rice, even partially overlapped BAC clones can be resolved on early pachytene chromosomes.[11] Pachytene FISH mapping also allows DNA probes to be mapped to specific euchromatic or heterochromatic regions. Pachytene FISH mapping of BACs anchored by genetically mapped DNA markers has become a powerful method to integrate genetic and cytological maps.[12,13]

FISH can be applied on extended DNA fibers. The correlation between the microscopic size of the fiber-FISH signals and the physical length of the extended DNA molecules ranged from 2.87 to 3.27 kb/μm from different reports.[11,14,15] DNA probes as small as few hundreds of base pairs can be used in fiber-FISH mapping.[14] Fiber-FISH can be used not only in fine mapping[11,15] but also in the analysis of repetitive DNA sequence structure[14] and complex DNA molecules.[16–18]

MOLECULAR MAPPING USING CYTOGENETIC STOCKS

Development of genetic linkage maps has become routine in plants because of the advances of molecular marker technologies. However, it is a challenge to integrate genetic linkage maps with specific chromosomes. The genetic linkage maps developed in the majority of the plant species are currently not integrated with cytogenetic maps. Aneuploids are valuable tools to integrate genetic linkage maps with chromosomes. A DNA marker can be assigned to a specific chromosome by comparing its hybridization intensity to a series of monosomic or trisomic lines.[19,20] The locations of the centromeres in the genetic linkage maps can be determined using telotrisomics or secondary trisomics.[21]

Mapping of cytogenetic stocks using genetically mapped DNA markers is a powerful approach to develop physical maps in plant species. The physical maps developed using this approach are fully integrated with genetic linkage maps. Weber and Helentjaris[22] were the first to demonstrate such a physical mapping strategy in maize. Using B–A translocation stocks, Weber and Helentjaris[22] mapped RFLP markers to specific maize chromosome arms and identified the chromosomal regions containing the centromeres. Using a similar strategy, Künzel et al.[23] developed physical maps in barley using translocation stocks.

Chromosomal deletion stocks were developed in wheat using the ‘‘gametocidal function’’ of an *Aegilops cylindrica* chromosome.[24] Most of the wheat deletion stocks lost only a terminal segment in one of the 21 chromosomes. Thus DNA markers located within the lost chromosomal segment can be readily determined using DNA blot hybridization. This ‘‘deletion mapping’’ strategy powerfully revealed the discrepancy between genetic and physical distances in a large complex genome.[25] Deletion mapping also led to the discoveries of recombination hot spots and chromosomal regions with high density of genes in wheat.[26,27]

‘‘Radiation hybrid mapping’’ is another physical mapping strategy based on cytological stocks. Individual maize chromosomes have been transferred into the genetic background of oat.[28] Irradiation treatment of the oat–maize chromosome addition lines resulted in radiation hybrids, oat lines possessing different fragments of the maize chromosomes including oat–maize translocation chromosomes and modified maize chromosomes with internal or terminal deletions.[29] Radiation hybrid mapping is strategically similar to deletion mapping and a DNA marker can be located to a specific chromosomal region based on the presence or the absence of this marker in a specific radiation hybrid.

CONCLUSION

Molecular cytogenetic mapping, which integrates molecular techniques into traditional cytogenetic mapping methods, has become an important genetic mapping methodology. With the molecular cytogenetic mapping approach it is now possible to identify and map individual chromosomes in virtually any plant species. More importantly, aneuploids and other cytogenetic stocks can now be more effectively used in genetic mapping.

Molecular Technologies and Their Role in Maintaining and Utilizing Genetic Resources

Amanda J. Garris
Alexandra M. Casa
Stephen Kresovich
Cornell University, Ithaca, New York, U.S.A.

INTRODUCTION

In the broadest sense, the goal of conservation activities is the preservation of diversity at ecosystem, community, and species levels. Conservation of plant genetic resources, with its focus on diversity within crops and their wild relatives, differs in that it is inextricably linked to a mandate for utilization. Perhaps the greatest challenge lies in identification of useful variation not readily assessed at the phenotypic level, due to the complexity of the trait or the masking effects of environment and genetic background. Exploitation of variation in collections has been achieved primarily through phenotypic screens and backcrossing strategies; however, molecular markers may serve to expedite the identification of useful alleles. It is not the scope of this article to provide a detailed description of molecular techniques, but rather to offer some insights on how understanding the structure of diversity allows the generation of data simultaneously useful for both conservation and use, enabling us to dissect gene function and consequently assess the predictive value of diversity for crop improvement.

CLASSES OF MOLECULAR MARKERS

Although morphological and biochemical markers (i.e., isozymes) still play an important role in understanding diversity, their low abundance and unknown selective neutrality have created a need for more specific DNA-based methodologies for characterizing genetic resources. In addition, the growing number of accessions present in germplasm banks has required faster and more cost-effective methodologies for understanding diversity and directing conservation efforts. Among the most widely used classes of molecular markers for germplasm characterization are restriction fragment length polymorphisms (RFLPs), randomly amplified polymorphic DNAs (RAPDs), amplified fragment length polymorphism (AFLPs), simple sequence repeats (SSRs), and more recently DNA sequence polymorphism. The choice of a marker technique will depend on several factors, including what is already known about the species (e.g., mating system and life form), the kinds of questions that are being addressed (e.g., levels of genetic diversity and distribution of variation), and infrastructure (i.e., amount of equipment required, start-up cost, and labor).

Molecular markers have been applied to most crop species in order to characterize the diversity present in nature, in farmers’ fields as well as in situ and ex situ collections. These data provide a means to quantify the level of diversity and how it is partitioned within a species, enabling conservation strategies that maximize diversity within collections through reduction of redundancy and identification of unique alleles. Applications include characterization of crop gene pools, identification of parentage, and selection of a representative core collection. Much emphasis has been given to the characterization of genetic resources; however, retention of diversity in collections requires effective maintenance strategies. Molecular markers provide a quantitative assessment of the level of diversity and can be used to monitor change over time in collections. In addition, they can provide a basis for setting priorities for additions to collections when used in concert with geographical information system (GIS), which could incorporate agroecological characteristics of collection sites and genetic diversity data to target potentially useful populations.

APPLICATION OF MOLECULAR MARKERS TO UTILIZATION OF GENETIC RESOURCES

Molecular markers, although widespread, have yielded few examples of successful identification of variation that can be exploited in breeding programs. However, population genetics approaches for identifying adaptive variation developed for noncrop species when applied to genetic resources collections may expedite the identification of useful alleles. Generally, these approaches interpret patterns of molecular diversity to evaluate evidence for a causative role in a phenotype, to identify genes for...
adaptation, or to predict phenotypic value. The discussion that follows highlights some approaches that use molecular diversity to identify genes of interest that could be utilized in genetic resources collections.

One promising approach is based on association genetics, in which the statistical association of sequence polymorphisms with a phenotype is evaluated. Developed for use in human genetics, association genetics has been successfully applied in maize. For example, a suite of polymorphisms in the Dwarf8 gene was found to associate with variation in flowering time.[5] The application of statistical analysis to the pattern of DNA polymorphism forged the link between molecular and phenotypic diversity in the case of this quantitative trait.

Another approach is to use patterns of molecular diversity to identify genes that have been targets of selection. Natural selection is expected to reduce diversity at a locus; this reduction in diversity is detectable in comparisons to an outgroup that has not been subject to the same selective pressure. Reduced diversity at SSR loci in maize relative to its wild relative teosinte has been used to identify candidate genes involved in domestication.[6] This approach could be modified to find targets of selection for adaptive traits by comparison of adapted germplasm within a crop. A complementary approach is to identify rapidly evolving genes underlying adaptive variation by their molecular diversity. The approach involves the screening of expressed sequence tags (ESTs) to identify those that have diversified compared to homologues in closely related species. In Drosophila melanogaster, this method has been used to identify putative targets of adaptive evolution.[7]

As the structural and active domains of proteins are better understood, it should facilitate in silico allele mining in genetic resources collections via analysis of which changes in DNA sequence will effect functional changes in the protein. This is a computational approach akin to reverse genetics, but uses naturally occurring variation in lieu of disruptions to form predictions about gene function. For example, a collection could be screened with primers to amplify the active region in a disease resistance gene to identify as candidates for further study variants that change the protein sequence.

LIMITATIONS

Although the application of molecular markers holds promise for genetic resources conservation and use, a few caveats should be noted. The methods outlined previously require substantial preliminary data on population structure and appropriate sampling. Patterns of diversity can be influenced not only by selection; the influence of population structure, linkage, and drift must be understood in order to correctly interpret results. Although these approaches can identify interesting candidate genes, functional studies will be required to establish causation. A greater limitation is that some differences that affect phenotype are not coded in DNA, including such phenomena as epigenetics and differential splicing of RNA transcripts. In addition, the importance of regulatory elements in plant evolution has been demonstrated, indicating that not only structural but regulatory genes will be important in conservation and breeding.[8]

CONCLUSION

Molecular markers have the potential to build the link between DNA sequence and phenotype, facilitating conservation and use as well as the link between them. Increased access to these technologies, in concert with improved computational methods for analysis, will make molecular techniques both more common and more useful in maintaining and utilizing genetic resources. In the future, important and challenging questions will not be restrained by the lack of appropriate tools, and the allelic diversity in crop collections can be implemented in crop improvement.

INTRODUCTION

Mutation is a permanent heritable change in the DNA of an individual organism. It is the ultimate source of all the biological diversity on earth. Life could not adapt and diversify without the substrate of heritable variation. In agriculture the exploitation of novel heritable variants has been the engine of plant and animal improvement. This article outlines the mechanisms that are responsible for heritable changes in DNA.

NUCLEOTIDE SUBSTITUTION EVENTS

Many different categories of mutation affect DNA molecules. The most regular form of mutational change is when one nucleotide is incorrectly replaced by a different nucleotide during replication (Fig. 1). These nucleotide substitutions are assumed to be stochastically regular in time. (Like radioactive decay, each mutation is assumed to arrive randomly, but with a constant probability in time.) Nucleotide substitution events are also assumed to occur with the same probability at every nucleotide site, independent of the nucleotide state at the mutated site or at neighboring sites. Much of our direct knowledge of the nucleotide substitution processes comes from the study of bacteria or viruses where many generations and very large populations of organisms can be studied in the laboratory. These studies indicate that the DNA replication process has a remarkably high fidelity, with a nucleotide substitution error rate on the order of one error per one billion replications per site (or $10^{-9}$ errors per site per generation).[1] These studies have also tended to validate the assumptions of constancy and independence previously mentioned. Estimates for eukaryotic organisms like crop plants and animals cannot be obtained from direct observation and must be calculated indirectly. Indel data.

Slipped-Strand Mispairing

Despite the fact that slipped-strand mispairing events are context-dependent and are usually inferred indirectly rather than observed, it is desirable to get some sense of the rate at which these kinds of events accumulate. The effects of replication slippage or slipped-strand mispairing generally cannot be observed directly and must be inferred based on the distribution of repetitive nucleotide sequence or base composition surrounding indels (Fig. 2). Estimates from Drosophila nucleotide sequence data suggested approximately 0.16 indels per nucleotide substitution.[3,4] Estimates based on chloroplast data from grasses suggested that indels and nucleotide substitutions contributed nearly equal proportions of total mutations; however, the authors point out that the relative contribution of indels with those from bacteria, indicating an average nucleotide substitution rate of roughly $4 \times 10^{-9}$ per site per generation.[1]
appears to diminish among more highly diverged species because of apparent superimposition of indels on previous indels.\(^5\) Slipped-strand mispairing appears to play a major role in indel generation, and may be particularly important in the proliferation of repetitive sequences, such as the short two- and three-base motifs that make up microsatellites.\(^6\)

**Unequal Crossover Events**

At tandemly repeated genes there is potential for out-of-register recombination, which can result in duplication, deletion, or truncation of a chromosomal region. Such events may be especially common in tandemly repeated arrays of genes such as nuclear ribosomal DNA.

**The Interaction Between Mutation and Recombination**

Genetic recombination is the process that disassociates mutations along a chromosome, typically through cross over—the breaking and reannealing of homologous portions of parental chromosomes during meiosis. A second form of recombinational exchange is commonly observed between different tandemly repeated gene family members. When such an exchange occurs, a mutant site on one repeated gene copy is transmitted to an adjacent gene copy, causing the repeated copies to become more similar in sequence than would otherwise be the case. This process is called concerted evolution. A related form of recombinational exchange that generates new alleles is observed in microsatellite loci where unequal exchange between tandemly arranged di- or trinucleotide repeats (or higher-order repeats) causes an increase or decrease in repeat number. Finally, unequal exchanges between repeated elements at different chromosomal locations can cause duplications and deficiencies of larger DNA regions.

**TRANSPOSON-INDUCED MUTATIONS**

Mobile elements (transposons) are a ubiquitous feature of plant and animal genomes. There are two broad categories of mobile elements: class I elements that replicate from an RNA intermediate via reverse transcriptase, and class II or DNA elements that replicate via a cut-and-paste mechanism. Both classes of elements are relatively common in plant and animal genomes. Class II elements tend to be associated with elevated transposition rates, but both categories are clearly implicated as causal agents in many mutations, owing to their ability to insert into or adjacent to genes, and thereby disrupt or alter gene function or gene expression.

One important aspect of transposon-mediated mutation is the ability to alter gene expression patterns. This may occur because the element has inserted into a 5’ UTR (untranslated region in the 5’ region of a gene) and has thereby disrupted transcription factor-binding sequence motifs, or it may occur because sequence motifs within the insertion act as novel sites for transcription factor binding. This latter capacity has been documented in a number of cases in plants and animals, and illustrates the creative acquisition of new gene expression patterns through the transposition of appropriate sequence features around the genome. The fact that transposable elements can move entire sequence motifs into new genic environments and induce novel patterns of expression tells us transposon mutation is modular and acts at a level beyond the individual nucleotide site.

**GENE DUPLICATION**

One of the important discoveries of the genomics era is the fact that many genes are redundant in plant and animal genomes. There are two broad categories of mobile elements: class I elements that replicate from an RNA intermediate via reverse transcriptase, and class II or DNA elements that replicate via a cut-and-paste mechanism. Both classes of elements are relatively common in plant and animal genomes. Class II elements tend to be associated with elevated transposition rates, but both categories are clearly implicated as causal agents in many mutations, owing to their ability to insert into or adjacent to genes, and thereby disrupt or alter gene function or gene expression.

One important aspect of transposon-mediated mutation is the ability to alter gene expression patterns. This may occur because the element has inserted into a 5’ UTR (untranslated region in the 5’ region of a gene) and has thereby disrupted transcription factor-binding sequence motifs, or it may occur because sequence motifs within the insertion act as novel sites for transcription factor binding. This latter capacity has been documented in a number of cases in plants and animals, and illustrates the creative acquisition of new gene expression patterns through the transposition of appropriate sequence features around the genome. The fact that transposable elements can move entire sequence motifs into new genic environments and induce novel patterns of expression tells us transposon mutation is modular and acts at a level beyond the individual nucleotide site.

**Fig. 2** Slipped-strand mispairing between noncontiguous repeats. Excision of the shorter single-stranded loop results in the sequence shown in the second alignment. Excision of the longer loop results in the third alignment. In the second and third alignments, the changed segments are underlined.
genomes. The processes that lead to the duplication of genes range from polyploidy (the doubling of entire genomes owing to the union of unreduced gametes, discussed next), to unequal crossover, to transposon-mediated transposition of genes. There are very few estimates of rates of gene duplication, but one recent estimate suggests a duplication rate of 0.01 per gene per million years.\(^7\)

Transposons are also implicated in the movement of genes or fragments of genes around the genome. This may occur as a consequence of reverse transcription of mRNA molecules or because a gene or gene fragment has been acquired within a mobile element. In either case it represents a kind of higher-level mutation that may provide adaptive flexibility by placing genes into new regions, possibly in association with entirely different expression signals.

**POLYPLOIDY**

In addition to gene duplication, polyploid formation can potentially induce or accelerate many of the mutational processes outlined in the foregoing discussion. Polyploidy is very common in flowering plants. Crop plants with polyploid origins include bananas, cotton, peanut, and wheat. In addition to extant polyploids, evidence of one or more rounds of ancient polyploid formation have been identified in species such as *Arabidopsis*\(^8\),\(^9\) and maize.\(^10\) Some of the ancient polyploid events appear to have occurred in lineages ancestral to the majority of flowering plants.\(^8\),\(^9\)

Polyploids are frequently the result of hybridization between well differentiated parental species. Thus, there is a potential for recombination, gene-conversion, and concerted evolution to occur between partially homologous chromosomes from the parental species. Transposons from one parental genome may also invade the genome of the other; with gene duplication, there is the potential for loss of duplicate gene function or even the elimination of coding DNA sequence.\(^11\)

**CONCLUSION**

Agriculture developed and flourished because humans learned how to exploit and maintain useful hereditary variants in a wide diversity of plant and animal species. Since the rediscovery of Mendelian genetics, a major research goal has been the acquisition of a detailed understanding of the mechanisms that generate hereditary variation. Our knowledge of the mutational process has grown enormously in recent years, revealing that mutation is a complex phenomenon with many mechanisms. One important lesson has been that mutation operates at various levels, ranging from nucleotide changes to transposition to gene duplication to the doubling of entire genomes. This rich variety of biological process has led to the wealth of mutational diversity that we seek to exploit in adapting plants and animals to human needs.

Mutualisms in Plant–Insect Interactions

W. P. Stephen
Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

Mutualisms are coevolutionary processes between pairs of organisms that impart joint benefits in the form of increased growth, reproduction, and survival. The relationship between the participants has evolved because the benefits gained are greater than the costs expended.

Mutualisms range from those which are ‘‘facultative,’’ in which each member gains a benefit but is not dependent upon the other, to ‘‘obligate,’’ in which one or both members is dependent upon the other for survival.

POLLINATION

Pollination involves the transfer of pollen from the anthers of one flower to the stigma of the same or a different flower. Nowhere is mutualism and coevolution more prevalent than in plant–pollinator interactions, and among pollinators insects reign supreme.

Flowers requiring insect pollination provide an abundance of nectar and/or pollen on a platform both visually and aromatically unique and attractive. Coevolution between flowers and insects—especially the bees—proceeded at a rapid pace, resulting in increased specialization in flowers to emphasize their identity and the concomitant specialization of pollinators to excel in their efficient utilization of that specialized resource. Although there are a number of insect groups other than bees that effect pollination (beetles, wasps, moths, flies, etc.) it is the bees which are most adept and abundant.

There are over 16,000 species and subspecies of bees in over 1200 genera worldwide, of which approximately 10% are social and 80% solitary. The social bees—Apis mellifera, Bombus spp., and the stingless bees—exist as long-lived colonies that have life spans which may endure for years, rather than weeks. Although workers in each colony utilize a wide array of pollen sources, individual pollen gatherers usually confine their activities to collecting pollen from one plant source during any single foraging trip and remaining faithful to that source as long as supplies exist. This transient specificity has probably arisen because of the mutual benefits it conveys to both plant and pollinator. The plant benefits from cross-pollination by bees bearing conspecific pollens, and the bees increase their efficiency in host location and pollen/nectar collection through the associative learning.

Few solitary bee species do not exhibit some degree of specificity to a particular genus or genus-group of plants. Relationships between partners, however, can be judged only by the fidelity shown by a specific pollinator in its pollen collection, for it is this behavior which defines the reproductive continuity of its plant host. Unlike social bees, solitary bees provision their cells with nectar-moistened pollen, and none amass nectar surpluses.

Coevolution between bees and their plant hosts has resulted in varying degrees of pollen collection specificity: polylecty (pollen is collected from many diverse plant hosts); oligolecty (pollen is limited to groups of related plant hosts); and monolecty (pollen is from a single plant species). These terms are relative for intermediate conditions are always found in evolutionary processes, yet they provide guidance.

Adaptations to their floral hosts have occurred in many of the oligolecistic bees. In the genus Diadasia (Anthophoridae) the hairs of the tibial scopa (areas evolved to transport pollen from floral hosts to nests) have undergone considerable modification to accommodate the various-sized pollen grains of their hosts. Most Diadasia that forage on Malvacaeae have modestly branched scopal hairs, whereas D. enevata, an oligolege on composites, has fine, densely plumose hairs to transport the small pollen grains common to that family. D. angusticeps is the only species of this genus found on Onagraceae, and its tibial scopae comprise stiff, nonplumose hairs that carry the cobweb-like pollen masses of the host. Unrelated genera such as Anthedonia, Diandrena, and Anthophora have species which are oligolecistic on Oenothera, and all possess sparse, simple, scopal hairs to accommodate the large Oenothera pollen with its interconnected viscid threads. Proteriades has hooked hairs on its mouthparts (maxillae) used to extract pollen grains from the small, slender corolla tubes of Cryptantha. Similarly, the foretarsi of Calliopsis (Verbena) have a series of curled bristles on their forelegs which can be inserted into the flowers of Verbena to scrape out the pollen and insert it on the regular pollen-carrying apparatus.¹,²

A number of obligate plant–bee associations exist. Dufarea versatilis has been found only on flowers of Mimulus nanus, Anthemurgus passflorae on Passiflora lutea, and Diadasia australis appears to collect both pollen and
nectar from *Opuntia*, rarely visiting other plants—even for nectar.

The foraging period of oligolectic bees is coadapted to the restricted flowering periods of their pollen hosts. Different species of the same bee genus may appear sequentially throughout the summer, utilizing entirely different pollen sources. In northern Utah, *Anthophora pacifica* appears in April and early May on *Astragalus* and stone fruits; *A. bomboides neomexicana* is on *Trifolium, Medicago*, and *Vicia* in June; *A. occidentalis* is on *Cirsium* in July; and *A. flexipes* is on late-summer composites in August.

Some species remain dormant for two or more years if the environmental conditions are unfavorable for either plant or insect activity. In 1961 a large nesting population of *Halictus* (Eeylauæ) aberrans failed to appear when their obligate host, *Oenothera latifolia*, failed to germinate. In 1962 *Oenothera* bloomed profusely and the bee was again present. It is not uncommon for a small number of diapausing prepupae of megachilid bees (*Osmia, Megachile*) to emerge during the second rather than the first year in that stage.

Bees with matinal (collect pollen in early morning prior to or at sunrise), crepuscular (collect pollen at dusk), or nocturnal (fly and forage at night) activities have adapted to meet the pollination requirements of their floral hosts. *Xenoglossa* collect pollen from *Cucurbita* at dawn; *Peponapis* work the same flowers in the early sunlight hours; and polyleges such as *Apis* and *Agapostemon* collect pollen until the flowers close. *Halictus* (Hemihalictus) lustrans is a matinal oligolege on *Pyrrophappus carolinianus*, the flowers of which close shortly after the sun strikes them in early morning.

_Halictus* (Specoedogastro) are common crepuscular bees, foraging on *Oenothera* in the early and late evening. The Indo-Maylasian subgenus *Xilocopa* (*Nyctome-lita*) forages much, if not most, of the night on nocturnal blooming plants.

The most remarkable diversity in flower form (paralleled with the obligate pollinators) is found among the orchids. This highly evolved plant group exhibits the most complex and precise adaptations to their pollinator partners of any plant group. Unlike most obligate cross-pollinated plants which rely largely on pollen-collecting females of various bee genera, the pollinating partners of orchids include wasps, beetles, fungus gnats, flies, moths, butterflies, and both males and females of solitary and social bees. The genome flexibility of orchids, especially in the tropical flora, has given rise to the speculation that many of the tight mutualistic associations may be more serendipitous than coevolutionary, or a combination thereof.

The single most complex mutualistic pollination relationship occurs in the fig (*Ficus* spp.) and its pollinator, the wasp, *Blastophaga* spp. (each species of fig has its own species of wasp). There are three types of saclike flower clusters in the fig, each consisting of numerous flowers on a fleshy receptacle. In the spring the first small structures develop, with male flowers located near the entrance and short-styled female flowers near the base. Spring females enter the flower and lay eggs in the ovules that develop into gall-like structures containing either females or wingless males. Males chew out of their galls and enter galls containing females. Upon mating the females leave the gall and become laden with pollen as they pass the male flowers at the fruit entrance. Females then move to the second receptacle type (the true fig), enter, and attempt to—but cannot—oviposit in the long-styled flowers characteristic of this stage. In the process the females pollinate enough of the flowers to yield the mature fruit. A third type of fruit cluster (mother fig), which contains only short-styled flowers into which the females oviposit, then develops on the tree. These develop into males and females, which enter diapause and emerge the following spring. In this system the wasp is not only the obligate pollinator, but also a parasite.

A unique obligate relationship exists between plants of the genus *Yucca* and *Tegeticula* moths. Adult yucca moths form the sticky pollen into a small pellet carried in modified mouthparts to the stigma of another yucca flower. Upon deposition of the pellet, the female deposits one to several eggs on the ovary. These hatch and the larvae burrow into the ovary to feed on the developing seeds. The plant tolerates the seed loss in return for pollination services from the adults. The moth consistently limits the number of deposited eggs per ovary and in so doing avoids exploiting its partner and throwing the system into imbalance. Early fruit abortion is a principal cause of yucca moth larval mortality, and it has been suggested that the quality and quantity of pollen provided by the moth are below that necessary for high fruit retention, also helping to promote evolutionary stability in the system.

**PROTECTION**

A landmark study on the obligate mutualistic relationship between the ant, *Pseudomyrmex ferringine*., and the bull’s-horn acacia, *Acacia cornigera*, was described from Central America. The ant provides protection to the plant and the plant, in turn, offers food and nesting sites. Queens of *Pseudomyrmex* bore holes through the hard covers at the thorn bases, excavate some of the pith, and establish their colonies. The colonies grow, occupying increasing numbers of thorns and often reaching populations of several thousand per tree. The ants provide defense against insect defoliators and clip off the vegetative
shoots that invade the acacia canopy. The acacia provides food in the form of high-protein Beltian bodies at the tips of some of its pinnate leaves, as well as sugar-rich nectaries at the leaf bases (Fig. 1). Both ant and plant have evolved traits to cement this association: Ants forage 24 hours a day rather than diurnally, and the plant retains its leaves even through the arid portions of the season. Neither ant nor plant can survive without the other in this ant–acacia relationship, although many other facultative ant–acacia associations occur.

Clear evidence of the antiherbivore defense in ant–plant mutualisms is provided in studies on three species of *Macaranga* which have either obligate or facultative relationships with a common ant. Plants, or parts of plants, that were kept ant-free for about one year lost 70–80% of their total leaf area, confirming the requirement of their ant partners for survival.[7]

There is normally a prompt response to the site of herbivore damage by the ant partner. In the obligate *Azteca* ant–*Cecropia* tree relationship there was a five-fold increase in the number of ants on damaged versus undamaged leaves, with activity peaking in 8–12 minutes after damage was inflicted.[8] Rapid recruitment was correlated with the number of ants patrolling the leaves, and the number of ants responding doubled when artificial damage was inflicted on the leaves. Damaged leaves on one tree prompted ant recruitment to leaves in adjacent *Cecropia*, suggesting interplant communication.

There is only one reported example of ants providing protection for an economically important plant. Ants live in close association with the cashew nut tree, *Anacardium occidentale*, which has nectaries on each leaf, the flower stalks, the base of each flower, and on the young nuts. Local ants living in the area ascend the tree to collect nectar, and in the process of foraging they will capture insect herbivore as they are encountered. Commerical crops of cashew nuts in Malaysia and Sri Lanka, solely protected by local ants, have been produced for as long as 20 years without the use of any pesticide.[9]

Most ants with obligate mutualistic associations require in situ nesting sites on their partners. These may be structures such as the greatly enlarged thorns of the bull’s horn acacia, or more commonly domatia (or caulinary domatia), expanded hollow stems. It is suggested that ants originally may have colonized later in plant development, when the diameters of the twigs were sufficient to accommodate small colonies. The advantages conferred by the presence of ants resulted in selective pressure for an earlier expression of the domatialike trait.

**DISPERAL**

Many ant species carry plant materials, especially seeds, over relatively long distances from the plant source to their nests. Although many of these seeds may ultimately germinate, the habits of these voracious generalist foragers do not fall within the framework of coevolution. However, in South Africa an intimate association has developed between ants and plants in the family Proteaceae that often results in seed dispersal. Many species in this family produce seed with a fleshy, edible appendage termed an elaiosome. Seeds are gathered by the ants and transported to their nests, where the elaiosomes are eaten. The inedible seed is either stored in the underground nest...
or discarded on the soil surface, where it may ultimately germinate and establish. The chaparral-like habitat of the fynbos is frequently swept by fires, after which only the seed in the underground nests will germinate.

Mycorrhizal Evolution

David M. Wilkinson
Liverpool John Moores University, Liverpool, U.K.

INTRODUCTION

The predominately mutualistic relationships between mycorrhizal fungi and vascular plants are very common; indeed, textbooks often cite figures suggesting that 80–90% of all vascular plant species are mycorrhizal. While such figures are approximate and based on extrapolation from a limited number of well studied examples, it is clear that mycorrhizae are widely distributed in modern plants, a fact that hints at a long evolutionary history for the relationship.

FOSSIL EVIDENCE

The fungal fossil record is relatively poor. While some spores are readily preserved, it requires unusual conditions to preserve hyphae (which are usually lacking in morphological features to aid identification even when preserved). However, there is now fossil evidence for arbuscular mycorrhizae contemporaneous with the origin of land plants. Important early fossils come from the Rhynine chert of the Lower Devonian age (approximately 400 million years b.p.), which contains well preserved terrestrial plant fossils. An example is Aglaophyton major, an enigmatic plant with features found in both vascular plants and bryophytes. Arbuscules (the sites of exchange of material between plant and fungus) are preserved in the fossilized tissues of this plant.[1]

Recently fossil evidence of fungal hyphae and spores similar to arbuscular mycorrhizae have been found from the mid-Ordovician.[2] These date from between 460 and 455 million years b.p. and were deposited in shallow marine conditions, presumably having washed in from nearby land. The Ordovician apparently occurred before the evolution of vascular plants and the terrestrial vegetation is poorly known, although it appears to have been dominated by plants similar to modern mosses and liverworts. However, the extent of terrestrial vegetation at the time is still controversial.[3] The fossilized fungal remains strongly resemble the modern genus Glomus. They suggest that such fungi predate the first vascular plants and may have been either free living or formed mycorrhizal-like relationships with the bryophytes. This second suggestion is supported by the facts that modern arbuscular mycorrhizae are known to form such relationships and that all modern Glomales fungi form mycorrhizae.[2] Other types of mycorrhizae appear to have developed much later,[4] although there is currently a shortage of fossil evidence.

IMPORTANCE FOR THE EARTH SYSTEM

Plants attempting to colonize the land would have faced the twin problems of desiccation and low nutrient substrates. Several authors have suggested that mycorrhizal relationships would have been crucial in surmounting these problems,[4,5] a hypothesis that has acquired the status of textbook orthodoxy. Particular emphasis has been placed on the role of mycorrhizae in acquiring phosphorus.[4]

If the mycorrhizal symbiosis was crucial in the development of widespread terrestrial vegetation, then it indirectly led to major global changes. Terrestrial plants caused the development of soils that retain water and, by maintaining a high surface area of damp mineral grains, greatly enhance chemical weathering. These reactions reduce atmospheric carbon dioxide and thus have important climatic implications.[3,6] As well as contributing to this process indirectly by supporting terrestrial vegetation, mycorrhizae directly contribute to weathering rates by producing organic acids and other chemicals that break down mineral material.[6]

EVOLUTIONARY MECHANISMS

The classic evolutionary problem with any mutualism is the question, why doesn’t one of the partners “cheat”? That is, why doesn’t one of them become parasitic, extracting resources from its partner without reciprocating by providing resources in return? There is a well established body of theory that can explain why mutualisms should be evolutionarily stable given certain assumptions such as vertical transmission of symbionts. However, these assumptions are not met by any of the various types of mycorrhizal symbioses. For example mycorrhizal fungi
are always acquired by horizontal transmission (from the environment) rather than by vertical transmission (directly from the parent, e.g., in the seed).[7]

There are a number of mechanisms that could lead to mutualisms based on horizontal transmission being stable;[7] one possibility is retaliation against cheating symbionts (e.g., by expulsion of fungi from the roots). Another is that local dispersal of plants (many seeds are only dispersed small distances) can lead to pseudovertical transmission. Here the plant acquires fungal partners from the soil that are genetically identical to those that infected the parent and so are equivalent to vertical transmission from an evolutionary perspective. It is also possible to view the acquisition of fungal symbionts by a plant as a biological market where the plant forms relationships with fungi that best suit current local soil conditions.[8] The potential importance of this latter mechanism is increased by the recent demonstration of very high levels of genetic diversity in arbuscular mycorrhizae at small spatial scales in some soils;[9] this could mean that the plant has a wide choice of potential fungal partners.

It is becoming increasingly likely that the evolution of mycorrhizae is a dynamic process with repeated gains and losses of the mycorrhizal condition over geological time. This position is supported by a recent molecular phylogeny[10] of ectomycorrhizal fungi. The evolutionary history of this phylum was reconstructed using 161 species (29% were mycorrhizal, the rest free living). This produced a large number of equally parsimonious trees; however, all of these showed repeated transitions between mycorrhizal and free living forms. This analysis strongly suggests that the relationship has arisen many times.

An additional complication in considering mycorrhizal evolution is the presence of genetically distinct nuclei coexisting in the spores of individual arbuscular mycorrhizal fungi.[11] This raises intriguing theoretical questions about what prevents competition between these different genomes. Consider the inheritance of organelles in eucaryotes: These are nearly always inherited from just one parent. The conventional explanation for this is that it removes the potential for conflicts of interest, which could arise if two genetically distinct lines of organelles were found within the same cell. Clearly, arbuscular mycorrhizae don’t use this strategy to eliminate the possibility of genetic competition. How they deal with this problem is currently an open question.

**MYCORRHIZAL NETWORKS**

It has become common for people to suggest that ecologically significant amounts of carbon may be moved from plant to plant through mycorrhizal networks, although the extent to which this happens is still controversial.[12] If such behavior is real this clearly raises a number of interesting evolutionary questions. Why should a fungus give away important resources to the plants and how can it be evolutionarily stable for a plant to give away resources to competitor plants? These questions have received little theoretical attention; however, Wilkinson[13] suggests some tentative answers. It may be to the advantage of the fungi to “invest” surplus carbon in plants that may become a future carbon source for the fungi. It is also possible to see a kin selection advantage in plants passing resources through mycorrhizal networks to nearby plants. Because many seeds only disperse short distances, many of these plants could be related to the donor. However, more complex explanations will be required if the mycorrhizal movement of carbon between different plant species is found to be common.[13]

**CONCLUSION**

The fossil record suggests that some forms of mycorrhizae have been important since the first terrestrial plants evolved. Indeed, they may have been crucial in this process, which laid the foundation for the complex terrestrial ecosystems we see today and had important implications for weathering rates and through these, for the Earth’s climate. One way of viewing the mycorrhizal symbiosis[8] is that it allows plants to adjust their root systems (which are often a complex of root and hyphae) to temporal and spatial changes in the soil. This allows them to adapt to local conditions with much more flexibility than would be possible by relying on their roots alone.

Symbioses with Rhizobia and Mycorrhizal Fungi: Microbe/Plant Interactions and Signal Exchange, p. 1213

**REFERENCES**

INTRODUCTION

Mycorrhizas (or mycorrhizae) are symbioses involving plants that become colonized by mycorrhizal fungi. There are several recognized types of mycorrhizas including arbuscular, ecto-, ectendo-, arbutoid, monotropoid, ericoid, and orchid. Each type consists of a unique combination of plant and fungal taxa. As has been well documented for the arbuscular, ecto-, and ericoid mycorrhizas, the symbioses may be mutually beneficial. For these mycorrhizas, the plant’s nutrient status may be improved as the fungus absorbs nutrients from the soil and transfers them to the plant. The fungus may also derive a significant amount of carbohydrate from the photosynthetic plant. From a human economic standpoint, the arbuscular and ectomycorrhiza are probably the most important mycorrhizal symbioses because these involve the majority of important food, fiber, and timber plant species, as well as many of the important edible fungi. These symbioses are also very important ecologically because most of the earth’s land surface is dominated by vegetation that is largely arbuscular mycorrhizal or ectomycorrhizal.

ARBUSCULAR MYCORRHIZA

Arbuscular mycorrhizas are formed when plants are colonized by members of the fungal phylum Glomeromycota, of which there are currently approximately 150 described species. The plants forming arbuscular mycorrhizas include many mosses, ferns, gymnosperms, and angiosperms. The arbuscular mycorrhiza is named for the arbuscule, a highly branched fungal organ usually produced within cortical cells of colonized plant roots. This is the organ across which the fungus absorbs carbohydrate from the plant, and the plant absorbs various nutrients from the fungus including Cu and Zn, possibly N, and especially P. In some cases, P uptake by roots may be downregulated as a consequence of the symbiosis, and the fungus may be the most important organ of phosphate absorption. In P-deficient soils, arbuscular mycorrhizal colonization can significantly improve plant growth and yield. The main reason for this is that phosphate usually occurs in low concentrations in the soil and diffuses slowly. The hyphae of the mycorrhizal fungi extending from colonized roots (Fig. 1) compensate for this by exploring a greater volume of soil than can the roots themselves and by presenting a greater surface area for phosphate uptake. Some, but certainly not all, arbuscular mycorrhizal fungi may produce other structures within the roots of colonized plants including vesicles, which are capable of storing high concentrations of lipid. Thus, some of the arbuscular mycorrhizal fungi are vesicular-arbuscular, or VA.

Common agricultural practices may strongly influence the efficacy of mycorrhizal colonization. For example, vigorous disturbance of the soil such as by tilling can disrupt the fragile fungal mycelium, and this can lead to a significant reduction in phosphorus uptake. Fallow periods can also lead to a reduction in viable mycorrhizal hyphae in the soil. Thus, the planting of mycorrhizal cover crops during normally fallow periods can lead to increased colonization of subsequent crops and to increased yield. Variation in root anatomy and root system architecture result in variation in the extent to which plants benefit from mycorrhizal colonization. Plant species that possess few root hairs, for example, are expected to benefit more from mycorrhizal colonization than do those whose roots are densely covered with long root hairs. Moreover, variation in the way different mycorrhizal fungi explore the soil and thus capture P may lead to variation in their effects on plant growth. In container plant production utilizing soilless media, the effectiveness of arbuscular mycorrhizal fungi may be much lower than in soil. In such production systems fertilizer may supply phosphate in high concentrations and the applied phosphate is often freely available because soilless media typically do not adsorb phosphate as do many natural soils.

ECTOMYCORRHIZA

Unlike the case with arbuscular mycorrhiza, the ability to associate with roots to form an ectomycorrhiza has developed independently in more than one fungal lineage. The several thousands of fungal species that form ectomycorrhizas include members of the Basidiomycota, Ascomycota, and Zygomycota. The plants forming
ectomycorrhizas are mostly angiosperm and gymnosperm shrubs and trees including members of the economically important and ecologically dominant Pinaceae, Fagaceae, and Myrtaceae. No fungal structures are produced within the root cells, but the fungus grows between the outer cortical and epidermal cells, and may form a dense mantle external to the epidermis. As it does so the root may cease to grow, giving rise to characteristic short mycorrhizal roots (Fig. 2). Hyphae extending from the surface of the mantle into the soil provide surface area for nutrient absorption. Thus, just as in the arbuscular mycorrhiza, this additional surface area can significantly increase the P status of the plant. N absorption may also be enhanced. The fungi also collectively possess a range of hydrolytic abilities that allows them to access some nutrient sources unavailable to uncolonized roots, including the ability to utilize some proteins, amino acids, amino sugars, and organic phosphates.\[1]\] Thus, the ectomycorrhizal fungi may be of particular significance in high latitude or high altitude biomes in which litter decomposition rates are relatively low and thus in which large fractions of the nutrients are bound up in organic forms. Ectomycorrhizal colonization may also be particularly important for developing seedlings that typically have poorly developed root systems. Some fungal species are capable of transporting significant amounts of water to the plant,\[8]\] the lack of which is responsible for a large fraction of seedling mortality.

It is widely recognized that a single tree in a natural ecosystem will be colonized by many ectomycorrhizal fungal species. A single-species plantation may support dozens of ectomycorrhizal fungal species. The causes of this diversity are only now being investigated, but the consequences to ecosystem function are already obvious. Variation among ectomycorrhizal fungi in their physiologies and morphologies give rise to variation in their functions. Whereas some are better at transporting N to the plant, others may be better at transporting P. Still others may be superior at water transport. Thus, nature may select for plants that support a variety of ectomycorrhizal fungal species. Most ectomycorrhizal fungal species produce macroscopic fruiting bodies such as mushrooms, puffballs, and truffles. Many are of great economic importance because of their edibility. These fruiting structures are also of great ecological importance because many serve as major food sources for a number of animal species.

**CONCLUSION**

Currently the arbuscular mycorrhizal fungi cannot be grown in pure culture. They are cultured on intact plants or on root organ cultures. Consequently, it is very costly to produce arbuscular mycorrhizal fungi for large-scale inoculation such as in field trials. Inoculation may only prove to be economically viable for crops of high value. For other crops, efforts to manipulate field practices to stimulate indigenous mycorrhizal fungi may be more practical. In temperate climates, for example, minimizing fallow periods and reducing soil disturbance are both effective ways to promote colonization by arbuscular mycorrhizal fungi of subsequent crops. In soilless media, such as in the floriculture industry, arbuscular mycorrhizal fungi may not prove to enhance P absorption, but it may influence other economically important traits such as disease resistance.\[9]\]

Nurseries of potentially ectomycorrhizal tree seedlings grown for reforestation or ornamental use may lack the...
most effective fungi following outplanting. A number of studies have shown that inoculation with appropriate ectomycorrhizal fungi improves survival and growth of tree seedlings.\textsuperscript{10} Thus, the view that inoculation of trees with ectomycorrhizal fungi can be helpful and economically viable is widely held. Indeed, there has been some effort to devise methods to artificially inoculate nursery beds and small seedling pots. Often spores or bits of sporocarp material are used as sources of inoculum. In some cases it is possible to grow ectomycorrhizal fungi in pure culture, allowing one to use vegetative mycelium as an inoculum source. Thus far, however, standard inoculum types, and the quantities and qualities of inocula have not been established for many specific tree species. The appropriate species of fungus must also be carefully selected because there is a wide range of specificity among ectomycorrhizal fungi for plant species.\textsuperscript{10} Other production methods including rate, form, and placement of fertilizer need to be established to encourage ectomycorrhizal colonization. Moreover, the economic benefit from inoculation needs to be established in more large-scale trials. Until then, inoculation may not become the standard silvicultural practice it probably should be.

Mycotoxins Produced by Plant Pathogenic Fungi

K. Thirumala-Devi
Nancy Keller
University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

Mycotoxins are natural, chemically diverse, fungal products that are defined by their harmful affects on humans and animals. Their existence came into the limelight in 1960 when more than 100,000 turkeys died in the UK as a result of consuming aflatoxin-contaminated peanut meal. Mycotoxins are introduced into the diet through consumption of contaminated produce and are toxic to human beings and livestock by exerting specific effects on a given organ system. Detrimental properties exhibited by mycotoxins include carcinogenesis, mutagenesis, teratogenesis, oestrogenesis and/or immunosuppression. Data suggest that exposure to two or more mycotoxins or an interaction between a mycotoxin and a pathogen exacerbates disease symptoms.

The majority of economically important mycotoxins are produced by Aspergillus, Penicillium, and Fusarium species, although other genera such as Claviceps also produce potent toxins. These genera are ubiquitous, and according to the Food and Agriculture Organization of the United Nations (FAO) over 25% of the agricultural commodities worldwide are significantly contaminated by mycotoxins. Although they are a postharvest problem, these fungi also cause significant preharvest contamination. In particular, contamination occurs in countries where climate and poor storage conditions favor the growth of mycotoxin-producing fungi. This article gives an account of a selected group of economically important mycotoxins and refers the reader to recent reviews and the Council for Agricultural Science and Technology (CAST) report published in 2003 for greater detail.

MYCOTOXINS PRODUCED BY Aspergillus AND Penicillium

Aspergillus and Penicillium species are closely related and can produce the same mycotoxins. These molds grow on a wide variety of food- and feedstuffs worldwide, especially cereals and oilseeds (Table 1, Fig. 1).

Aflatoxins

Aflatoxins are a group of polyketides produced by Aspergillus flavus and A. parasiticus on a variety of crops. The highest levels of contamination have been recorded in peanuts, maize, Brazil nuts, pistachio nuts, cottonseed, and copra. Lower levels are recorded in almonds, pecans, walnuts, raisins, spices, and figs. The four aflatoxins (AF)—AFB1 > AFG1 > AFB2 > AFG2 (ranking based on toxicity)—are the most common, and of these AFB1 and AFG1 are most frequently found in foods. AFM1 (derived from AFB1) contaminates dairy products. Aflatoxins target the liver and immune system, causing hepatocellular carcinoma especially in humans who are infected with the hepatitis B virus. Aflatoxins can also cause several pathological effects on various other organs and tissues.

Sterigmatocystin is the penultimate precursor of AFB1 and is produced most commonly by A. nidulans and A. versicolor. It contaminates cereal crops and milk products, including cheese. Sterigmatocystin is hepatotoxic and carcinogenic; nevertheless its toxicity is one-tenth that of AFB1.

Ochratoxins

Ochratoxins are a group of dihydroisocoumarins produced by A. ochraceous and Penicillium verruculosum on a diverse group of crops including barley, oats, rye, maize, wheat, coffee, nuts, olives, and grapes. Ochratoxins bind tightly to serum albumin and are carried in animal tissues and body fluids. Consequently, they can be detected in sausage derived from contaminated meats. Ochratoxin A, the most toxic member of this group of mycotoxins, has been shown to be nephrotoxic, hepatotoxic, teratogenic, carcinogenic, mutagenic, and immunosuppressive. Of greatest concern for human health is its implicated role in an irreversible and fatal kidney disease referred to as Balkan Endemic Nephropathy. Ochratoxin A has also been shown to contaminate human milk, and thus can cause kidney disorders in breast-fed infants.
Cyclopiazonic Acid

Cyclopiazonic acid is an indole tetramic acid produced by several Penicillium species, including *P. cyclopium*, *P. aurantiogriseum*, *P. crustosum*, *P. griseofulvum*, and *P. camemberti*, as well as the Aspergillus species *A. flavus*, *A. tamari*, and *A. versicolor* on maize and peanuts. [11] Cyclopiazonic acid often co-occurs with aflatoxins and causes necrosis of the liver, spleen, pancreas, kidney, and salivary glands.

MYCOTOXINS PRODUCED BY *Fusarium*

*Fusarium* species are pathogens on a wide variety of crop plants throughout the world. They cause mainly stem and root rots and frequently infect the grain of cereal crops. Several species of *Fusarium* produce mycotoxins on a range of cereal crops, which include wheat, maize, rice, barley, and oats.

Fumonisins

Fumonisins are pentahydroxyicosanes produced by *F. verticillioides* and *F. proliferatum* on maize and sorghum. Fumonisin B1, the most toxic fumonisin, promotes cancer and causes equine leukoencephalomalacia [12] and porcine pulmonary edema. [13] A high incidence of human esophageal cancer in South Africa and China has been correlated with the presence of fumonisins in foods. Fumonisins exert their toxic effects by altering sphingolipid metabolism. In laboratory tests fumonisins induced cancer of the kidney and liver in rodents.

Trichothecenes

T2 toxin and deoxynivalenol (DON) belong to a large group of structurally related sesquiterpenes known as trichothecenes.

T2 toxin is produced by *F. sporotrichioides* on barley, maize, oats, and wheat. It can severely damage the entire digestive tract and cause rapid death due to internal hemorrhage. It is also implicated in pulmonary hemo/siderosis. Damage caused by T-2 toxin is irreversible.

DON is probably the most widely occurring *Fusarium* mycotoxin, contaminating a variety of cereals, especially maize and wheat. It is most frequently produced by *F. graminearum*. The outbreak of emetic syndromes in livestock due to the presence of DON in feeds has resulted in coining the name "vomitoxin." It is implicated in outbreaks of acute human mycotoxicosis in India, China, and rural Japan. However, DON is much less toxic than T2 toxin.

Zearalenone

Zearalenone is a β-resorcylic lactone produced by *F. graminearum* on maize, wheat, and other cereal grains. It

is produced along with DON and has been implicated in the outbreaks of acute human mycotoxicosis. Exposure to zearalenone-contaminated maize elicits estrogenic effects in the mammalian reproductive system and has specifically been associated with hyperoestrogenism in livestock (especially pigs), characterized by vulvar and mammary swelling, infertility, and abortions.

MYCOTOXINS PRODUCED BY Claviceps purpurea

Ergot is the common name of the disease caused by Claviceps purpurea, a fungus that occurs on rye and other small grains, where it replaces the kernel with a fungal body called a sclerotium. The sclerotium contains ergot alkaloids that when ingested cause toxic reactions, including convulsions, hallucinations, and dry gangrene, that lead to loss of limbs. Epidemics of ergotism have been recorded throughout history. This often fatal condition has since been traced to the presence of alkaloids, derivatives of the four-ring-structure ergoline, in the sclerotium.

GENETIC AND MOLECULAR BIOLOGY OF MYCOTOXIN BIOSYNTHESIS

Aflatoxin and sterigmatocystin biosynthesis is the most thoroughly characterized of any mycotoxin. Molecular genetic analyses of three species of Aspergillus have resulted in the cloning of an aflatoxin/sterigmatocystin gene cluster containing all of the enzymatic genes and at least two regulatory genes required for aflatoxin/sterigmatocystin biosynthesis. In general, it appears that genes for fungal secondary metabolism are found in clusters; the trichothecene, fumonisin, and ergot alkaloid gene clusters have also been described. Furthermore, additional studies of aflatoxin/sterigmatocystin biosynthesis have shown that mycotoxin formation is genetically linked to asexual spore production through a G protein/cAMP/protein kinase A signaling pathway. Gene cluster expression is also subject to regulation by environmental parameters including nitrogen and carbon source and external pH mediated through the global regulators AreA, CreA, and PacC, respectively.

CONTROL

Regulation of the moisture content of crops is the most effective postharvest management control of mycotoxin formation and is successfully used in developed, but not developing, countries. Preharvest contamination remains a problem worldwide, although some recent success has been documented by using atoxigenic Aspergillus flavus strains as biocontrol agents. Crop plants which can suppress mycotoxin biosynthesis or resist fungal entry may offer a long-term viable option for reducing mycotoxin contamination. Several research groups are focusing both on traditional plant breeding and on development of engineered plants to reduce mycotoxin contamination.

Once contamination occurs it is not economically feasible to reduce the mycotoxin content of foods. However, potent adsorbents such as activated clays have successfully been used by the feed industry in developed countries to minimize the influence of aflatoxins on livestock.

CONCLUSION

Mycotoxin contamination of foods and feeds has assumed economic importance globally because of its influence on the health of human beings and livestock. This article has given a brief account of the chemical nature of mycotoxins; the deleterious effects caused by economically important mycotoxins; progress in the molecular genetics of mycotoxin biosynthesis; and existing control strategies. Clearly, given the importance of this disease problem, additional controls are needed. Current research focused on identification and characterization of fungal and/or plant genes and gene products important in the production of mycotoxins should yield insight toward the development of additional control strategies.

INTRODUCTION

Natural rubber is an essential part of society used in the manufacture of over 40,000 products, more than 400 of which are medical devices.\(^1\) Over 2000 rubber-producing plant species have been described; however, historically only two—the Brazilian rubber tree (\textit{Hevea braziliensis}) and guayule (\textit{Parthenium argentatum})—have been exploited commercially.\(^2\) The Brazilian rubber tree at present is the only commercial source of this essential natural plant product.\(^3\)

Natural rubber is a renewable resource accounting for approximately 40\% of the world’s total rubber consumption,\(^4\) the remainder coming from synthetic rubber, a nonrenewable resource derived from petroleum. Synthetic rubber cannot substitute for natural rubber in applications that require high elasticity, resilience, and/or minimum heat buildup (e.g., high-performance tires and medical latex products).\(^5\) Because of these characteristics, the global demand for natural rubber continues to increase,\(^1\) but in the future, because synthetic rubber is a nonrenewable petroleum product, even more natural rubber will be required to replace synthetic rubber’s market share.

Having more than one source (biodiversity) of natural rubber is desirable, especially to meet the anticipated need of this essential natural product. At this time guayule has the greatest potential of the over 2000 rubber-producing plants to become an additional commercial source of natural rubber, mainly because of the extensive research and development that have already taken place. Commercialization of guayule would not replace the production of rubber from the Brazilian rubber tree, but would increase total global rubber production.

NEED FOR INCREASE IN BIODIVERSITY OF RUBBER PRODUCTION

Growing guayule as a commercial source of natural rubber would lead biodiversity as well as help stabilize global rubber production. The Brazilian rubber tree is grown exclusively in tropical climates,\(^5\) today commercial production is centered almost exclusively in Asia.\(^1\) Guayule is a xerophytic shrub native to the Chihuahuan desert of north-central Mexico and southwestern Texas;\(^2\) commercial production would be in arid and semiarid environments. The Brazilian rubber tree is grown almost exclusively from clones, which are extremely narrow genetically. This makes the crop particularly susceptible to crop failure due to disease, as in the case of the South American industry’s decline due to leaf blight.\(^3,5\) Guayule populations contain a great amount of genetic diversity, making them ideal for selecting plants best suited for cultivation in different areas and environments. Guayule also has a very complicated reproductive system that continually generates genetic diversity among progeny of a single plant.\(^5,6\)

It appears the demand for natural rubber will continue to grow at a rate greater than can be met by new plantings of the Brazilian rubber tree; changing political climates in production areas can also jeopardize the continuity of the natural rubber supply. Growers in developing countries are moving away from plantation farming of the Brazilian rubber tree to higher-value agricultural crops.\(^3\) Guayule, on the other hand, has the potential to add jobs in rural areas with arid and semiarid environments where traditional agriculture is becoming less economical because of water and salt problems. The commercialization of guayule will enhance the sustainability of agriculture in these rural areas, and will benefit more than growers through the concurrent development of local processing facilities and manufacturing plants. Because guayule would be grown in other environments and areas of the world, its production would ensure the continued flow of this essential natural product.

NATURAL RUBBER/LATEX

Natural rubber is an isoprenoid molecule, related to plant compounds essential for plant growth and development.\(^7\) Its desirable qualities are due to its molecular structure and high molecular weight.\(^5\) In the Brazilian rubber tree, natural rubber in the latex form is produced within subcellular rubber particles in a pipelike system of laticifers, from which the latex can be harvested by tapping.\(^8\) Natural rubber latex in guayule is produced within rubber particles found within the cytoplasm of intact bark parenchyma cells, and does not flow from continuous ducts as in the Brazilian rubber tree.\(^5\) Grinding the stem tissues
and using solvents in order to free the rubber molecules affect extraction of rubber latex in guayule.

Many commercial, medical, transportation, and defense industries are dependent on natural rubber in the production of their products. Although the development of synthetic rubber by the chemical industry after World War II was a great breakthrough, synthetic materials have not been able to achieve the same properties as natural rubber for many high-performance applications.  

GUAYULE AS A POTENTIAL RUBBER-PRODUCING CROP

Guayule has been known as a source of natural rubber since pre-Columbian times, its first use dating to the production of rubber balls for indigenous people’s games in present-day Mexico. In the early 1900s, guayule was considered an alternative source of natural rubber in the United States due to the high price of rubber imported from the Amazon region. This initial interest resulted in the first of three major efforts to domesticate and commercialize guayule.

This initial attempt started with the harvesting of wild guayule stands in Mexico, and accounted for up to 24% of the total rubber imported to the United States by 1910. At this time, up to 20 extraction plants were either operational or under construction in Mexico, when production came to a halt in 1912 because of the Mexican Revolution. Production then moved across the border to the United States, with efforts centered in Arizona and California. This first effort to commercialize guayule came to a halt in 1929 as a result of the Great Depression.

The second major effort to utilize guayule as a source of natural rubber was the Emergency Rubber Project of World War II. Natural rubber production had moved almost exclusively to large plantations of the Brazilian rubber tree grown in Southeast Asia, and these sources were cut off at the beginning of the war. The Emergency Rubber Project was very successful. It generated the bulk of our knowledge about the basic biology of the guayule plant and developed the germplasm on which current breeding programs are based. The effort ended with the end of the war and the development of synthetic rubber.

Guayule was seriously investigated a third time in the early 1970s, when crude oil prices quadrupled. The fear was that if the oil supply could be manipulated, there might again be a shortage of natural rubber due to either natural disaster or political unrest in Southeast Asia. This led in the United States to the enactment of the Native Latex Commercialization and Economic Development Act of 1978. A tremendous amount of work was again accomplished, resulting in significant yield increases and the refinement of cultural practices to fit modern mechanized agriculture. This third effort again showed that guayule could be planted, cultivated, harvested, and processed as a source of natural rubber. However, as the political climate changed, this effort was also terminated, and guayule was again considered a source of natural rubber only in times of emergency.

This appeared to be the end of guayule’s commercialization efforts. To be considered a commodity in direct competition with the Brazilian rubber tree, guayule rubber would have to either perform the same functions at lower cost or perform better at the same costs. Although guayule rubber is equivalent in quality to the Brazilian rubber tree latex, it was not competitive economically. However, guayule is once again being considered for commercialization because of the occurrence of latex allergy in the general population.

PRESENT POTENTIAL FOR GUAYULE COMMERCIALIZATION

Allergic reactions are a result of protein contaminants in rubber products, and range from contact dermatitis to anaphylactic shock when susceptible individuals come in contact with these proteins. With over 400 medical devices containing natural rubber, this is potentially a very serious problem. Guayule latex contain’s low levels of proteins, none of which elicit an allergic response in subjects who are sensitized to Brazilian rubber tree latex proteins. Therefore, guayule affords a potential new product—hypoallergenic latex—to be used as an alternative in the manufacture of products for individuals with latex allergy. A method to extract natural rubber in latex form from guayule has been developed, and the goal of producing hypoallergenic guayule latex products is moving toward becoming a reality.

CONCLUSION

Natural rubber is an essential part of life in today’s society. The demand for natural rubber will continue to increase because of both increased consumption and the eventual need to replace synthetic rubber. At this time the Brazilian rubber tree is the only source of commercial natural rubber. Thus there is a need for additional sources to expand the growing range and worldwide production. At this time guayule is the most promising plant to fill this niche. Guayule makes a natural rubber of at least the quality required for high-end uses, such as high-performance tires and medical products, but it is not directly economically competitive with the Brazilian rubber tree in
these markets. However, guayule makes natural rubber latex that is nonreactive to individuals synthesized to proteins found in Brazilian rubber tree latex products. Thus, guayule has the potential to become a commercial crop for the production of hypoallergenic latex products.

INTRODUCTION

Nematodes are an extremely successful group of thread-like, worm-shaped animals that are found in many ecological niches, including extreme environments. They may be the most abundant multicellular animals, occurring as parasites of plants and animals and as free-living nematodes feeding on bacteria, fungi, and protozoa. This article presents a description of nematode history and anatomy, including size relationships, life cycle, general external and internal anatomy, survival, and feeding habits.

DISCUSSION

Nematodes are a remarkably successful group of thread-like, worm-shaped invertebrate animals adapted to survival in most ecological niches. Because they require water for locomotion, they occur in marine and freshwater environments, in the film of water between soil particles, and in plant and animal tissues. Nematodes also are found in extreme environments such as desert and polar regions. They may be the most abundant multicellular animals, and the more than 20,000 described species occur as parasites of plants and animals—including humans—and as free-living nematodes feeding on bacteria, fungi, and protozoa. They are inconceivably abundant and can be found in the most unexpected places, forming a recognizable world with all plant and animal life and geographical landmarks visible, even if all the matter on the earth except nematodes were somehow swept away.[1]

A rich history of nematodes derives from early writings on symptoms, signs, and treatment of large human parasitic nematodes, especially *Ascaris*, a large intestinal roundworm. The oldest writings describing these maladies are from the Chinese culture and date back to about 4700 years ago. References to nematodes were also recorded during the dominant civilizations of the Middle East and Mediterranean areas over 2000 years ago. The advent of the microscope in the 17th century resulted in many contributions to the science of nematology. The 18th and early 19th centuries were a time of historic discoveries in nematode anatomy, embryology, taxonomy, and life cycle studies of animal and human nematode diseases, including elucidation of the principles of alteration of generations, intermediate hosts, and vectors. During this time, the study of nematode parasites of livestock and other domestic animals flourished, and the seriousness of the many human diseases caused by nematodes was established.[2]

The study of plant-parasitic nematodes has a relatively recent history dating back only to 1743, when John Turbevill Needham, a clergyman interested in science, observed nematodes emerging from distorted grains of wheat. This seed gall nematode, *Anguina tritici*, had seriously affected wheat yield in the great Middle Eastern civilizations. Over 100 years elapsed until the plant pathologist Julius Kühn described an eelworm disease that caused stunting of teasel, a plant whose spiny fruit were used to raise the nap on wool. Only two years later, a serious disease of sugar beet in Europe was determined to be caused by the nematode later named *Heterodera schachtii*. Discovery of another European nematode-induced disease on potato soon followed. Investigations on controlling these and other nematode pathogens dominated nematological research in Europe for about 40 years. The basic principles of disease management tactics such as soil fumigation and crop rotation were established during this period are still applicable today.[3]

The word nematode means “threadlike” in Greek and amply describes the appearance of these animals, especially the smaller forms when dispersed in a vial of water. Nematodes are nonsegmented, unlike earthworms for example, and are spindle-shaped, tapering slightly at both ends. Plant-parasitic species vary from about 0.3 μm long in the genus *Paratylenchus* to about 5 mm in the genus *Longidorus*. The longest mammalian parasite occurs in whale placenta and reaches 8 meters in length. Females in
some plant-parasitic genera are kidney-shaped, lemon-shaped, pear-shaped, or otherwise swollen as adults, whereas the males remain vermiform (worm-shaped).

Plant-parasitic nematodes exhibit a simple, direct life cycle that usually includes egg, four juvenile, and adult stages. Nematodes are usually bisexual, existing as distinct males and females. Some nematodes, however, are hermaphroditic, and the female sex organs produce both sperm and eggs that combine during fertilization. In another variation, called parthenogenesis, males (and spermatozoa) are not required for reproduction, although males may be present in the population.

The nematode oral aperture is surrounded by six lips, or fewer if they have become partly combined as in more derived genera. There is typically a single papilla on the inner edge of each lip adjacent to the mouth, and two on the outer side of each lip in some ancestral forms. Certain marine nematodes, which are thought to be ancestral, have the inner row of papillae on the lips surrounding the mouth, an adjacent row of setae, and an outer row of larger setae. Plant-parasitic nematodes have few papillae, no setae, and combined lips that have taken on new forms.

The nematode head skeleton supports the lip region and is composed of radial blades and basal ring, which appear light or dark depending on the degree of hardening. The mouth is the beginning of the alimentary canal and it is followed by the buccal cavity or stoma. In plant-parasitic nematodes the buccal cavity is armed with a hollow, protrusible stylet or mouth spear (http://www.barc.usda.gov/psi/nem/what-nem.htm). The stylet is the most distensible structure in the head; its shape varies among the genera of plant-parasitic nematodes and can often be used to determine the nematode genus (http://nematode.unl.edu/key/nemakey.htm). The stylet is hollow for part of its length and is used to withdraw nutrients from plant cells. It also can serve as a conduit for digestive gland secretions into the plant cell. The stylet has protractor muscles attached at the base and forward at the anterior wall of the esophagus. Contraction of these muscles thrusts the stylet out of the mouth and into the host plant cell.

The stoma, or mouth cavity, is followed posteriorly by the esophagus, composed of the corpus, the isthmus, and a basal glandular region. The corpus can be further subdivided into the anterior procorpus, followed by the metacorpus, which may or may not contain a distinctive valve. A very narrow (<1 μm) food channel, called the lumen, passes through the esophagus and connects it with the intestine. The metacorpus in plant-parasitic nematodes is often furnished with radial muscles, making it a pump chamber that can pulsate up to several times per second. This pump chamber with its valve withdraws nutrients from cells in the active feeding phase and passes the nutrients through the valve into the intestine. Depending on the nematode, there may be an initial passive-feeding phase that does not require the pumping of the metacorpus to feed the nematode. The esophageal lumen is tri-radiate as it passes through the metacorpus and has one ventral and two subdorsal rays when relaxed. When the radial muscles contract, the lumen becomes more circular and food passes posteriorly. The isthmus that follows the metacorpus is a narrowing of the esophagus before the basal glandular portion of the esophagus. The morphology of the esophagus is one way in which nematodes are identified and is especially important for plant-parasitic genera. The plant virus vectors Xiphinema, Longidorus, Trichodorus, and closely related genera have a two-part esophagus, consisting of a narrow anterior portion and an expanded basal glandular portion.

The excretory system of more ancestral nematode forms may contain an H-shaped system of lateral ducts ending in a cuticularized duct and anterior ventromedian pore. Plant-parasitic genera in the class Secernentea (containing most of the plant parasites) may have a duct or a portion of a duct on one side leading to a ventral excretory cell, or the more advanced forms may have only the ventral cell, excretory duct, and pore. Adenophagean nematodes have only the single ventral cell, without collecting tubules (ducts), and a noncuticularized excretory duct leading to the outside pore. There is some debate on whether this system is solely for the function of excretion or possibly also for osmoregulation or secretion of materials other than wastes.\[^{4,5}\]

The female reproductive system is divided into ovary, oviduct, and uterus. There are one or two ovaries composed of an anterior germinal zone where eggs are produced and an ovum growth zone. If a globular spermatheca for the storage of sperm is present, it is part of the uterus.\[^{6}\] The tubular reproductive system opens through the ventral vagina and vulva. The tubular male testis joins posteriorly with the digestive system to create a common duct called a cloaca that opens ventromedially through the anus. Males have one or two testes and an external pair of hooklike spicules used to open the vulva during copulation. There may be a spicular guide piece called a gubernaculum and another accessory piece called a telamon (capitulum) adjacent to the spicules on the anterior side.

Nerve cells in the nematode are grouped into ganglia that in turn are grouped into a circumesophageal commissure (nerve ring), a collection of coordinated nerve cell bodies that become the primitive nematode “brain.” Nerves extend anteriorly toward the mouth and provide chemosensory and tactile information to the nematode. Nerves also extend posteriorly in the dorsal and ventral hypodermal cords and provide chemosensory and tactile sensation. The main nerve is the ganglionated ventral nerve.
Nematodes have an external covering called a cuticle, a nonliving, proteinaceous, multilayered covering secreted by an underlying living, cellular hypodermis (“tissue below the skin”). In order to accommodate growth-necessitated expansion, the passage of a nematode from one juvenile stage to another (or to the adult stage) is accompanied by molting, a process during which the new cuticle is synthesized and the old cuticle is shed. The physiological and biochemical control of nematode molting has not yet been elucidated, unlike the molting process in insects. In many plant parasites, the old cuticle substantially dissolves and is probably absorbed by the hypodermis. The hypodermis invaginates in four sectors and forms cords that contain a limited number of hypodermal cells, separating the bands of muscle fibers into quadrants of two subdorsal and two subventral bands. Nematodes are unique in that the muscle cells send out innervation processes to the nerve cell body, rather than the more typical arrangement of nerve cell axons providing transmission of electrical impulses to the muscles. For most nematodes, muscles of the body are limited to longitudinally oriented fibers.

The ability of nematodes to thrive in a variety of habitats results from their anatomy and physiology. The selective permeability of the nematode cuticle often facilitates the entry of nutrients or the export of wastes, yet impedes the entry of detrimental compounds. Many nematodes can survive extended periods of drought or temperature stress via morphological and biochemical adaptations, such as the accumulation of the sugar trehalose and other specific molecules. The eggs of some plant-parasitic nematodes can survive for years in soil; eggs often hatch when stimulated by exudates from host plants. Identification of these so-called hatching factors is an active research area; only one such chemical has been identified to date.

Although some plant-parasitic nematode species climb on and penetrate the aerial parts of plants, most plant-feeding nematodes are root pathogens. Some of these move through plant tissues and feed on different roots, whereas others become established in a permanent feeding site. These sedentary root parasites greatly alter the physiology of host roots. Their esophageal glands secrete proteins and possibly other factors that cause structural and physiological modification of the host cells the nematodes feed upon.

The free-living nematode species Caenorhabditis elegans was the first multicellular animal to have its genome completely sequenced. This nematode contains more than 19,000 genes, although their functions are as yet largely uncharacterized. Analyses comparing the sequences of genes from C. elegans to those of plant- and animal-parasitic nematodes are yielding insight about the function of genes important in parasite development and pathogenesis (http://elegans.swmed.edu/genome.shtml).

Nematodes possess the same biochemical pathways present in most animals. Unlike their mammalian and plant hosts, nematodes cannot biosynthesize heme or steroids; unlike all other animals, nematodes possess a glyoxylate cycle that enables them to biosynthesize carbohydrates from their storage lipids. Although many nematode parasites of mammals extensively catabolize organic molecules anaerobically and produce short-chain fatty acids as waste products, carbohydrate catabolism in plant-pathogenic species is primarily aerobic, via typical tricarboxylic acid and electron transport pathways.

Nematode Feeding Strategies

Richard S. Hussey
University of Georgia, Athens, Georgia, U.S.A.

INTRODUCTION

Plant-parasitic nematodes have evolved diverse parasitic strategies and feeding relationships with their host plants to obtain nutrients that are necessary for development and reproduction. Depending on species, these biotrophic parasites feed from the cytoplasm of unmodified living plant cells or have evolved to modify root cells into elaborate, discrete feeding cells. These parasitic nematodes use a hollow, protrusible feeding structure called a stylet to penetrate the wall of a plant cell, inject esophageal gland secretions into the cell, and withdraw nutrients from the cytoplasm of the parasitized cell. Certain species take up cytosol from the parasitized cell directly through a minute perforation created in the plasma membrane at the stylet orifice, while others ingest nutrients through a feeding tube.

NEMATODE FEEDING STRATEGIES

Plant-parasitic nematodes have evolved diverse parasitic strategies and feeding relationships with their host plants to obtain nutrients that are necessary for development and reproduction. Depending on species, these biotrophic parasites feed from the cytoplasm of unmodified living plant cells or have evolved to modify root cells into elaborate, discrete feeding cells. These parasitic nematodes use a hollow, protrusible feeding structure called a stylet to penetrate the wall of a plant cell, inject esophageal gland secretions into the cell, and withdraw nutrients from the cytoplasm of the parasitized cell. Plant-parasitic nematodes can be separated into four general groups according to the evolution of their mode of parasitism: migratory ectoparasites, sedentary ectoparasites, migratory endoparasites, and sedentary endoparasites (Fig. 1). The migratory ectoparasites are the most primitive mode of parasitism, directly feeding from unmodified root cells. In contrast, the more evolutionarily advanced sedentary endoparasites have evolved a very specialized mode of parasitism, dramatically modifying root cells of susceptible hosts into elaborate, unique feeding cells, including modulating complex changes in cell morphology, function, and gene expression. The amount of tissue destruction and the degree of plant response are often related to the type of feeding relationship between the nematode and its host. The migratory ectoparasites remain outside the root and insert their protrusible stylet to feed either on epidermal cells or cells deeper within the root. As a rule, species that possess a short stylet (e.g., Tylenchorhynchus spp.) feed on epidermal cells, while species with a long stylet (e.g., Belonolaimus spp.) are able to exploit tissues deeper in the root. With the exception of species of a few genera (e.g., Belonolaimus) that feed on root tips, nematodes with this type of feeding strategy generally cause little obvious tissue damage. Sedentary ectoparasites feed from a single site or root cell for a prolonged period of time while remaining outside the root. Feeding by Criconemella xenoplax causes little tissue damage, but other species, such as Hemicyclocyphora arenaria, induce terminal galls when feeding at root tips.

Another group of nematodes, the endoparasites, invades root tissue with part or all of their body. Although some endoparasites feed as soon as they enter the root, other species feed only after migrating to a preferred feeding site. Migratory endoparasites (e.g., Pratylenchus and Radopholus spp.) enter roots and feed on cells as they migrate intracellularly through the root tissue. These endoparasites inhabit primarily the cortical tissue of roots. Migratory endoparasites possess a small but robust stylet which is first used to pierce the walls of root cells and then to withdraw food from the cytoplasm. This feeding behavior causes extensive destruction of root tissue along the path of the migrating nematode. Sedentary endoparasites (e.g., Meloidogyne, Globodera, and Heterodera spp.) have evolved very specialized and complex feeding relationships with their host plants, feeding from a single cell or a group of cells for prolonged periods of time. These nematodes invade roots as vermiform second-stage juveniles. Those of the Meloidogyne species move within the intercellular space in the cortex and those of the Globodera and Heterodera species migrate intracellularly within the root cortex. Further nematode development depends upon the elaborate modification of the phenotype of vascular cylinder cells to form specialized feeding cells that become the sole source of nutrients for the parasites.1,2 The association of feeding sites with the root vascular cylinder supports a more concentrated and
sustainable supply of nutrients. When feeding commences, the second-stage juvenile grows and becomes saccate and immobile. In this feeding strategy, destruction of root tissue is usually limited to cells around the feeding site and the endoparasitic nematode.

In addition to the protrusible stylet, plant-parasitic nematodes have a well-developed esophagus for feeding on plants. In tylenchid nematodes, which are the most important plant parasite group, the esophagus has a muscular metacorpus containing a triradiate pump chamber.

Fig. 2  Fine structure of the *Criconemella xenoplax*–feeding cell relationship. A. Cross-section of a feeding cell (FC) in the cortex of a tomato root. The nematode stylet (S) penetrated between two epidermal cells (EC) and was inserted into the feeding cell without penetrating the plasma membrane (arrowhead). A zone of the cytoplasm of the feeding cell is modified around the stylet tip. A profile of the cell’s nucleus (N) is visible. B. Detailed view of the opening created in the plasma membrane (PM), which was invaginated around the stylet (S) tip when the membrane (arrow) became tightly appressed (arrowhead) to the wall of the stylet orifice. (From Ref. 8.)
and three large and complex secretory gland cells. The transcriptionally active gland cells, one dorsal and two subventral, are the principal sources of the secretions involved in plant parasitism. During secretion, the gland cells release secretory proteins stored in granules into the lumen of the esophagus to be injected through the stylet into host tissue. Changes in the esophageal gland cells during the parasitic cycle indicate various roles for the gland’s secretory proteins during different stages of parasitism. The nature of nematode esophageal gland secretory proteins and their function in parasitism is now beginning to emerge.

Nematode feeding from root cells is a very deliberate process and can be divided into distinct phases that include stylet insertion, injection of esophageal gland cell secretions, ingestion of nutrients, and stylet retraction. The feeding phases of migratory and sedentary parasites are similar, but each phase—and particularly nutrient uptake—is considerably longer for the sedentary than for the migratory feeders. When a potential feeding site is selected by the nematode, the wall of the root cell is penetrated by the stylet, which remains protruded and in contact with the cell cytoplasm during the secretion and ingestion phases. During the secretion phase, secretory proteins synthesized in the esophageal gland cells pass through the stylet into the parasitized cell. After cessation of the secretion activity, rapid maximum dilation of the metacorpal pump chamber creates the suction necessary for the nematode to withdraw nutrients from the cytoplasm of the feeding cell through the stylet lumen. When the metacorpus ceases pumping to terminate the ingestion phase, the stylet is retracted from the plant cell to end the feeding cycle. However, the sedentary ectoparasitic and endoparasitic nematodes establish a prolonged biotrophic feeding association with the elaborate feeding cells they induce. During feeding, the sedentary nematode inserts its stylet through the wall of the parasitized cell without piercing the plasma membrane, which becomes invaginated around the stylet tip. Initially in the feeding cycle, esophageal gland cell secretions that may modify the cell are injected through the stylet. Certain species (e.g., C. xenoplax) take up cytosol of the parasitized cell directly through a minute perforation created in the plasma membrane at the stylet orifice, while others (e.g., root-knot or cyst nematodes) inject nutrients through a feeding tube.

Feeding tubes are formed within the cytoplasm of parasitized root cells from stylet secretions injected by sedentary endoparasitic nematodes (Globodera, Meloidogyne, Heterodera, Rotylenchulus spp.). These unique structures are used by the nematode to efficiently withdraw nutrients from the feeding cell. Feeding tubes formed by M. incognita females are 1 μm wide and up to 110 μm long with a uniform lumen of approximately 450 nm diameter (Fig. 3). The distal ends of feeding tubes are closed. The sedentary endoparasitic nematodes feed in cycles from the modified cells and a new feeding tube is formed each time the nematode reinserts its stylet into the parasitized cell to initiate a new feeding cycle. Feeding tubes are formed from dorsal gland cell secretions injected into the cytoplasm of the parasitized cell through a pore in the plasma membrane. Feeding tubes function in facilitating the transport of soluble nutrients from the cytosol of the feeding cells to the stylet orifice. For M. incognita, which inserts its stylet only 2 to 3 μm through the wall of the feeding cell without piercing the plasma membrane, the long feeding tube provides the nematode access to more of the cytoplasm of the feeding cell than would be accessible if the nematode used only its stylet to
withdraw nutrients. The sealed distal end of the feeding tube and the lack of noticeable wall perforations suggest that the wall of the feeding tube is permeable to soluble assimilates. Microinjection studies, in fact, show that feeding tubes function as a molecular sieve during ingestion of nutrients from the feeding cell by the nematode.}\[6\]

INTRODUCTION

There is in general an inverse relationship between initial nematode population densities and annual plant growth and crop yield. This relationship results in nematode population assessment being crucial for their management. Assessing nematode populations often involves an initial diagnosis and quantification of diverse kinds and numbers present, after which specific taxa within the nematode community may be monitored. The diversity of nematode species with different morphology, modes of reproduction, survival mechanisms, and feeding habitats increases the challenges of this endeavor.

DISCUSSION

Nematodes that attack higher plants are obligate parasites, and a number of important species within certain genera may vector plant viruses. Ectoparasitic nematodes feed from the outside of plants by inserting stylet into root tissue. Some of these nematodes may become sedentary and may feed on a specific group of cells for an extended period of time, whereas others are browsers and move frequently about the root surfaces as they feed. The latter nematodes are migratory ectoparasites. In contrast, other nematodes invade plant tissues where they feed internally. Nematodes that move throughout cortical or other tissues are called migratory endoparasites, whereas the sedentary endoparasites induce elaborate modifications of certain cells, giving rise to highly specialized feeding sites that are essential for nematodes’ life cycles (Fig. 1).

Nematode infestation of soil and infection of plants may be assessed by sampling associated soil and/or plant tissue and extraction of the nematodes from those samples. Infected plant tissue also may be stained to render endoparasitic nematodes readily visible via microscopy. An effective nematode assessment should be accurate, rapid, simple, sensitive, and quantitative at the species/subspecies level. Light microscopic examination of extracted specimens is still the primary means of species identification and quantification. Nematode species identification generally is based on rather specific morphological structures.[1,2] However, differential plant-host responses and biochemical and molecular characteristics are becoming increasingly important for nematode diagnosis; the integration of these techniques with traditional morphological data is ongoing.[3–7]

SIGNS AND SYMPTOMS

The facts that most plant-parasitic nematodes are microscopic, inhabit the soil, and induce relatively nonspecific plant symptoms add to the challenges encountered in assessing their infestation. Assessment of nematode pathogens that attack stem or foliage tissues is less difficult but requires awareness of the potential for this type of disease agent. Thus, associated symptoms and signs of nematode infection are often helpful in initial phases of assessing related maladies. Foliage-infecting nematodes induce specific aboveground symptoms. For example, *Aphelenchoides besseyi* incites the development of pale yellow or white leaf tips on rice, whereas *Ditylenchus dipsaci* causes extensive distortions and swellings of infected tissues on alfalfa and other crops. The key general symptom of nematode infestation is irregular growth patterns within a field and/or a general decline and dieback. The latter often occurs on perennial crops such as fruit trees or ornamentals, e.g., *Radopholus similis* on banana or citrus trees.

Belowground symptoms of nematode infection range from large root galls induced by *Meloidogyne* spp. to root-surface necrosis caused by the migratory endoparasite *Pratylenchus* spp. Surface lesions are also caused by ectoparasites such as *Xiphinema* spp. and *Belonolaimus longicaudatus*. Some of the ectoparasitic nematodes, including *Paratrichodorus minor*, induce characteristic modifications of root size and shape, such as stubby roots. Signs of nematode may include structures such as cysts of *Heterodera* and *Globodera* and egg masses of *Meloidogyne* and *Rotylenchulus*, both of which can be observed on plant roots without a microscope. Thus, an initial assessment might include foliage or root signs and...
symptoms. Sample collection, extraction, and identification of key nematode species, however, should follow this type of preliminary assessment.

**SAMPLING**

A representative sample is crucial for qualitative and quantitative assessment of nematode infestation, whether soil or plant tissue.³,⁸ An excellent sample also is essential for molecular-based as well as traditional nematode-assessment procedures. Generally, a pre-determined number of subsamples of soil is collected with a cylindrical sampling tube and bulked before extraction. The exact number of subunits (cores) is determined for a given area by the purpose of the assessment. For example, soil samples composed of 20 to 30 subunits from 2 hectares (ha) may provide assessments that fall within 50% of the mean of the population levels. However, much greater sample numbers and volume of soil are needed for highly precise assessments.⁹ The timing of sample collection is even more critical for securing meaningful data. In temperate and tropical regions, populations of nematodes, especially *Meloidogyne* spp., decline sharply in the absence of a host. Thus, detection failures may be encountered for certain nematodes unless sampling is performed within the root zone at mid to late summer, at harvest, or within a few weeks after harvest. The timing of sampling is less critical for cooler regions where population decline is less severe and with cyst nematodes.

**EXTRACTIONS AND BIOASSAYS**

The biology and life cycle must be considered in selecting the specific extraction procedures (Fig. 1). Assessments of

---

infestation of ectoparasitic nematodes are limited to soil extractions, whereas most affected soil and/or plant tissue may be assayed for endoparasites. Life stages that occur in soil and/or in plant tissue range from mobile to quiescent forms and include juveniles, adults, cysts, individual eggs, egg masses, and various combinations. Numerous methods for extracting nematodes are available. For most extraction procedures, nematodes are separated from soil by a combination of flotation and sieving, or they are encouraged to emerge from plant tissues by being placed in a wet environment. Specialized extraction procedures are also available for assessing nematode eggs (especially in those highly damaging species, *Meloidogyne*, *Globodera*, and *Heterodera*.)

An appropriate host plant can be used in performing a bioassay for assessing low-level infestations, genetic variants, or related host resistance, and for assessing nematicide efficacy for highly aggressive nematodes, including species of *Meloidogyne*, *Globodera*, and *Heterodera*. Biosassays are invaluable in assessment of nematode races/pathotypes that may attack given sources of host resistance. For an immediate assessment of potential tissue infection by these parasites, a tissue stain such as acid fuchsin-glycerin or cotton blue-glycerin greatly enhances the visibility of endoparasites via microscopy. The gelatinous egg matrix or egg mass produced by *Meloidogyne* spp. may be stained with phloxine B to facilitate the quantification of these structures on plant roots.

**Nematode Identification**

For a detailed treatment on species identification, the reader is referred to the earlier article by J. G. Baldwin that addresses classification and identification of nematodes. Currently, identification of these parasites is based largely on morphology and in some instances on cytology, host response, biochemistry, and molecular diagnostics. As discussed earlier, symptoms and signs on plants may be characteristic of certain nematode species, but identifications should be confirmed by more precise criteria. In addition to nematode morphology, differential host tests are important for assessing infestation of certain nematode species. For many root-knot nematode populations, the North Carolina differential host test has been used widely to differentiate the common species *M. arenaria*, *M. hapla*, *M. incognita*, and *M. javanica*, as well as related host races. This system is especially useful for cropping systems that include peanut, cotton, corn, soybean, and tobacco. In another widely used host-nematode system, 16 host races of *Heterodera glycines*, based on four soybean-genotype differentials, are central to characterizing genetic variants in given fields and facilitating the development of new breeding lines/cultivars with resistance to this pathogen. The subspecies designation system for *H. glycines* was recently revised to include seven host differentials with field populations placed in "HG Types."

**APPLICATION OF BIOTECHNOLOGY IN NEMATODE ASSESSMENT**

After more than a century of taxonomic research on nematodes, only an estimated 10% of all nematode biodiversity has been characterized, primarily morphospecies. Although morphology continues as the primary focus in nematode identification, protein and nucleic acid analyses offer much for the future. These emerging approaches to assessment and characterization of nematode species and populations offer much for advancing our understanding of nematode biodiversity, general ecology, and population assessment for management and regulatory purposes. Molecular methods for nematode identification could be more objective and reliable than traditional systems. Also, molecular probes may be suitable for any life stage present in a sample.

Electrophoretic enzyme phenotypes have proven to be a practical means for identifying species and/or subspecies of *Anguina*, *Meloidogyne*, *Globodera*, *Heterodera*, and *Radopholus*. The utility of identification of the common *Meloidogyne* species using isozyme phenotypes has been particularly effective in the root-knot nematode research projects. For example, *M. arenaria*, *M. incognita*, *M. javanica*, *M. mayaguensis*, and *M. naasi* can be distinguished via esterase phenotypes. Differential esterase alleles also have proven useful for demonstrating multiple matings among inbred lines of *H. glycines* as well as tracking crosses of certain inbred lines of that species. In addition to the isozyme phenotypes, differences in 2-D protein patterns have proven useful for separating species and infraspecies or variants of *Globodera*, *Heterodera*, and *Meloidogyne*. Unique proteins are available that could be used to develop serological kits for detection. Monoclonal and/or polyclonal antibodies have been developed for *Bursaphelenchus*, *Ditylenchus*, *Globodera*, *Heterodera*, and *Meloidogyne*. For example, species-specific proteins were used to develop monoclonal antibodies for distinguishing *Globodera rostochiensis* and *G. pallida* in immunooassays. These monoclonal antibodies, in addition to separating the two species when used in an ELISA, have potential for the quantitative determination of potato cyst nematodes in soil samples. This technology...
has great potential for use in regulatory as well as diagnostic and management programs.

The range of techniques now available for studying DNA has resulted in much progress in characterizing genomic, mitochondrial, and ribosomal DNA of nematodes. In addition to advancing our understanding of nematode phylogenetic relationships, this rapidly expanding information also provides useful tools for nematode diagnostics (Fig. 2). For molecular diagnostic assessments, the objective is to obtain low-cost, user-friendly, reliable molecular data that distinguish nematode species or subspecies levels. The DNA techniques developed and utilized in the diagnostic purposes include amplified fragment length polymorphisms (AFLP); specific oligonucleotide probe; microsatellite and repetitive DNA; polymerase chain reaction (PCR) and multiplexed PCR; randomly amplified polymorphic DNA (RAPD); restriction fragment-length polymorphisms (RFLP); ribosomal DNA (rDNA) intergenic (IGS) and internally transcribed (ITS) spacer region PCR-RFLP and sequence; sequence-characterized amplified region (SCAR); sequence tag site (STS); and variable number tandem repeat (VNTR). In addition to assaying the sedentary endoparasite nematodes Globodera, Heterodera, Meloidogyne, Nacobbus, and Cactodera, specific DNA diagnostic methods have also been applied to migratory ecto- and endoparasites such as Anguina, Belonolaimus, Bursaphelenchus, Criconemella, Ditylenchus, Hoplolaimus, Helicotylenchus, Pratylenchus, Radopholus, and to the virus vector nematodes Longidorus, Trichodorus, and Xiphinema.

CONCLUSION

Based on the ongoing molecular characterization of nematode-plant interactions, the above approaches should prove fruitful for species and population-level assessment of these important crop pathogens.

INTRODUCTION

Secretions from the stylet (hollow mouth spear) of phytonematodes mediate the process of plant parasitism, including nematode penetration and migration within host plant roots, and dramatic transformations of plant cells into permanent feeding sites for the nutrition of sedentary nematode life stages. The stylet secretions are produced in three elaborate esophageal gland cells that have evolved to enable plant parasitism by tylenchid nematodes. The genes expressed within the gland cells that encode the stylet secretions are termed parasitism genes. The nature and number of parasitism genes in phytonematodes identified to date has been somewhat surprising, and includes significant evidence that phytonematodes may have acquired some of their parasitism genes from other organisms.

PARASITISM GENES

The primary morphological adaptations of nematodes for parasitism of plants include a protrusible stylet (hollow feeding spear) connected to three elaborate esophageal secretory gland cells (Fig. 1). These adaptations allow nematodes to feed on plant cells directly from outside plant roots (as ectoparasites) in soil or to penetrate plant roots (as endoparasites) to modify and feed from internal plant tissues (see R. S. Hussey, this volume). Although the genes that control the formation of the stylet have evolved to promote plant parasitism, it is the genes that encode the secretions synthesized in the esophageal gland cells that control the dynamic interaction of the nematode with its plant host.[1,2] Changes occur within sedentary nematodes during plant parasitism—including atrophy of the two subventral esophageal gland cells shortly after feeding site formation—and the concomitant increase in the size and activity of the single dorsal esophageal gland cell (Fig. 1). Products from the nematode gland cells may be secreted through the stylet (Fig. 2) into plant tissues for relatively simple feeding processes such as the predigestion of plant cell contents by some ectoparasitic nematodes, or for the complex processes of plant tissue penetration and feeding site formation by some sedentary endoparasitic nematodes. The potential range of functions of nematode secretions and their regulated expression during plant parasitism make the genes that encode nematode esophageal gland secretions the primary parasitism genes of plant-parasitic nematodes.[3]

The isolation of nematode stylet secretions to analyze their components has been difficult because the nematodes are microscopic in size and they are obligate parasites. Monoclonal antibodies have been generated that bind to specific secretory proteins within the esophageal gland cells of both cyst and root knot nematodes (Fig. 2), and the antibodies have demonstrated that the proteins can be secreted through the nematode stylet and that the gland cell secretions change during the course of plant parasitism.[1] One gland-specific monoclonal antibody was used to immunopurify a protein produced in the subventral esophageal gland cells of both the soybean cyst nematode (Heterodera glycines) and the potato cyst nematode (Globodera rostochiensis). The amino acid sequence of the purified gland protein was used to design degenerate oligonucleotides to obtain cyst nematode complementary DNA (cDNA) clones from the cyst nematodes that encode the subventral gland protein. Database searches indicated that the cDNA clones encoded [beta]-1,4-endoglucanases (cellulases)—the first endogenous cellulases to be isolated from animals.[3] It was further demonstrated that the cellulases could degrade a carboxymethylcellulose substrate,[5] that the cellulases are secreted into plant tissues (Fig. 3) by cyst nematodes,[4] and that the cellulases are expressed exclusively within the cyst nematode subventral gland cells only during the motile life stages.[5] Interestingly, [beta]-1,4-endoglucanases (and likely other cell wall-modifying enzymes) of plant origin are upregulated in nematode feeding sites when the nematodes become sedentary.[6] The data strongly supported a role for cellulase secretion by cyst nematodes to facilitate their penetration and intracellular migration in plant roots but not for feeding site formation. One striking feature of nematode cellulase genes was their strong similarity to bacterial cellulase genes and relatively weak similarity to cellulases of eukaryotic origin or to any genes identified in the model nematode Caenorhabditis elegans.[7] Because the nematode origin of the cellulases was confirmed by both in situ localization studies and analyses of nematode cellulase genomic clones, microbial contamination was ruled out. It has been postulated that one
potential origin of the cellulase genes in plant-parasitic nematodes was ancient horizontal gene transfer from prokaryotes.\cite{1,3}

Cloning of several other genes encoding secretions from the esophageal gland cells of plant-parasitic nematodes supports the hypothesis that some nematode parasitism genes—particularly those expressed in the subventral gland cells—may have been derived via horizontal gene transfer. Subtractive hybridization procedures were used to enrich a pool of cDNA clones from the root knot nematode, *Meloidogyne javanica*, for genes expressed in the esophageal gland cell region.\cite{8} One gene that was demonstrated to be exclusively expressed in the esophageal gland cells of *M. javanica* during plant parasitism was homologous to bacterial chorismate mutase.\cite{8} The nematode chorismate mutase gene was able to complement function in a bacterial chorismate mutase-deficient mutant. A cDNA clone derived from the parasitic stages of *Meloidogyne incognita* by RNA

fingerprinting encoded a predicted cellulose-binding protein with homology to bacterial cellulose binding domains, and its expression was localized within the nematode’s subventral esophageal gland cells. Genes from cyst nematodes that encode the cell wall–degrading enzyme pectate lyase are also expressed in the subventral gland cells of infective stages, and the nematode pectate lyases have their greatest similarity to pectate lyases of bacteria and fungi.

Although the examples of potential horizontal acquisition of some nematode parasitism genes have been unexpected, the likelihood that some endogenous nematode genes have evolved roles in plant parasitism is great. It is also clear that large-scale isolation and identification of genes expressed in parasitic nematodes is a more efficient and comprehensive way to isolate parasitism genes than to isolate and purify secreted nematode proteins. Expressed sequence tags (ESTs) provide partial sequence of random cDNA clones from a given library, which can be used for homology searches and genemapping efforts. cDNA libraries can be generated from whole nematodes of any chosen life stage for direct EST analysis, but the identification of potential parasitism genes (i.e., gland genes) becomes difficult unless the random sequences provide an obvious database homologue (i.e., cellulase, pectinase, etc.). One strategy to narrow the search for parasitism genes is to differentially compare genes expressed in whole nematodes between preparasitic and parasitic life stages—to see what genes are turned on in the nematode during parasitism. This was the basis of the RNA fingerprinting strategy that isolated the cellulose-binding gene expressed in the subventral gland cells of *M. incognita*. It also has been observed that the activity and contents of the esophageal gland cells of *G. rostochiensis* change in preparation for plant parasitism when infective juveniles are incubated in potato root diffusate (PRD). A cDNA-AFLP method was used to compare genes expressed in juveniles that were incubated in water and juveniles that were incubated in PRD, and a number of genes specifically upregulated in *G. rostochiensis* from PRD treatment were isolated and confirmed to be expressed specifically within the nematode’s esophageal gland cells.

A tissue-specific way to isolate nematode parasitism genes is to directly target the genes expressed within the nematode esophageal gland cells. The chorismate mutase gene (mentioned earlier) expressed in the gland cells of *M. javanica* was isolated by differentially screening cDNA from sections of nematode esophageal gland regions and (glandless) tail regions that were manually dissected. However, the most direct method has been to exclusively microaspirate the contents of nematode esophageal gland cells and use the gland cell mRNA in RT-PCR to create gland cell cDNA libraries. Contents of the esophageal gland cells microaspirated from mixed parasitic stages of *H. glycines* were used to generate a cDNA library that profiled gene expression in the gland cells during the entire parasitic process. Gland cell cDNA clones that contained a secretion signal peptide were selected using a specialized vector in yeast, and 14 unique secretory *H. glycines* gland cell cDNA clones were identified. mRNA in situ hybridization was used to demonstrate that a number of the clones were specifically upregulated within the dorsal gland cell of parasitic stages of *H. glycines* (Fig. 3), but not within preparasitic stages. Another gland-cell cDNA library prepared similarly from mixed parasitic stages of *H. glycines* was used in suppression subtractive hybridization (SSH) against cDNA from the tail region to yield 23 unique clones from the gland cell library. A LD-PCR cDNA library prepared from the same *H. glycines* gland cell cytoplasm was used to obtain full-length clones of the gland cell cDNAs. Sequences of the full-length clones indicated that 10 unique cDNA clones contained a predicted signal peptide, and mRNA in situ hybridizations demonstrated that four of the clones with signal peptides were expressed specifically within the esophageal gland cells of *H. glycines*.

The initial attempts (discussed earlier) to select genes from the *H. glycines* esophageal gland-cell cDNA libraries suggest that the libraries are an enormous source of potential nematode parasitism genes—worthy of extensive EST analysis without prior selection. Bioinformatics development and analysis will be a key component to deduce potential nematode parasitism genes among the many clones, and a scheme to prioritize candidate parasitism genes has been developed. Database homology searches using the Basic Local Alignment Search Tool (BLAST) algorithm may immediately suggest candidate genes with potential function in parasitism. cDNA clones that contain complete 5’-end sequence can be analyzed by the SignalP and PSORT II algorithms for the presence of signal peptides and predicted subcellular (i.e., extracellular) localization, respectively. These analyses provide a manageable number of cDNA clones for high-throughput mRNA in situ hybridization to confirm the expression of secretion genes within the nematode esophageal gland cells. For example, one *H. glycines* gland-cell library cDNA clone that had homology to a hypothetical *C. elegans* protein in BLAST analysis, and a second cDNA clone that had homology to a salivary proline-rich glycoprotein of *Rattus norvegicus*, both had predicted extracellular (secreted) localization by PSORT II and were confirmed to be expressed in *H. glycines* esophageal gland cells by in situ hybridization. In other cases, however, sequence of *H. glycines* gland-cell library cDNA clones provided no database homologues (i.e., pioneers) using BLAST analysis, yet the encoded peptides were
predicted to be secreted and were expressed exclusively within the dorsal esophageal gland cell of only parasitic stages of *H. glycines*.[12]

**CONCLUSION**

As bioinformatic analyses are improved and functional assays for candidate nematode parasitism genes are developed in the near future,[1] our understanding of the molecular basis of nematode parasitism of plants will accelerate. Knowledge of the function of nematode parasitism genes will present multiple targets for intervention in the parasitic process and lay the foundation for the development of novel strategies to reduce nematode damage to crops.

Nematode Population Dynamics

Robert McSorley
University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Population dynamics focuses on the rise and fall of nematode population numbers over time. Nematode population changes are somewhat predictable, although patterns vary depending on whether crops are annual or perennial. The host status of the crop to plant-parasitic nematodes is critical in determining rates of nematode buildup or decline. Many other biological, physical, and chemical factors affect nematode population dynamics. Knowledge of population dynamics is important in planning crop rotations and sequences with minimal nematode damage. However, much additional biological information may be needed to understand population dynamics in specific sites and situations.

IMPORTANCE OF NEMATODE POPULATION DYNAMICS

Plant-parasitic nematodes cause serious losses on many different crops, and in many instances, thresholds for damage to crops by nematodes have been estimated. Above the threshold population density—tolerance limit—the severity of nematode damage increases as population density increases. Properly collected soil samples can reveal the kind and number of nematodes present and indicate whether the threshold for damage has been exceeded. Although nematodes can be moved from place to place in soil or on equipment, they cannot migrate easily on their own. Therefore, the nematode population density in a site is unlikely to be changed much by immigration or emigration, and population growth or decline within the site determines most future trends in nematode population levels.

NEMATODE POPULATION GROWTH OVER TIME

If population density of a plant-parasitic nematode on a favorable host crop is plotted over time, population growth may follow a logistic growth curve (Fig. 1). Individual points typically show deviation from the theoretical logistic curve due to sampling error. Population growth from low initial densities may be quite rapid, approaching exponential growth. Ultimately, population growth slows and population density levels off as a carrying capacity—or equilibrium density (E)—is reached. Fluctuations in population growth may be particularly severe as E is first approached, with population density stabilizing over time.

Annual Crops

On an annual crop, the population growth curve (Fig. 1) may correspond with the life cycle of the crop. Once the crop is removed or the roots deteriorate, population levels may fall due to lack of a host or may increase to even greater levels if the next crop planted is a better host and has a greater E value. Over a long period of time, nematode population densities will appear as a sequence of peaks and valleys, increasing to the equilibrium densities appropriate for favorable crops and conditions, and decreasing if poor hosts are grown or during winter or fallow periods.

Perennial Crops

Long-term fluctuations in nematode population levels occur on perennial crops as well. Seasonal growth flushes of active feeder roots provide feeding sources for nematodes and opportunities for population growth. Populations may decline as older roots senesce or as plants approach winter dormancy. Because a root food source may be present most of the time, it is difficult to determine whether nematode population fluctuations are influenced directly by key environmental factors such as temperature and moisture or indirectly by the effect of these factors on root growth.

NEMATODE HOST STATUS

An impression of the host status of a crop cultivar relative to a particular nematode species can be obtained by examining the relationship between the initial population density (P_i) and the final population density (P_f) reached after a constant time interval. The life span of an annual crop is often used as a convenient time interval. If P_f > P_i, then the nematode population has increased on that crop,
and the crop could be considered a host of the nematode. A comparison of $P_f/P_i$ for a group of different crop cultivars could be used to provide a comparison of which cultivars were good hosts or poor hosts. However, the relationship between $P_f$ and $P_i$ may be too complex to make such straightforward comparisons.\[^{[5]}\] If the natural logarithm of $P_f$ is plotted against the natural logarithm of $P_i$ across a range of different $P_i$, a curved relationship typically results, leveling off at $E$ (Fig. 2). At a very low $P_i$, a cultivar may appear to be a good host ($P_f > P_i$), but at a very high $P_i$, the same cultivar may appear to be a poor host ($P_f < P_i$). The potential for population increase is much greater if $P_i$ is low than if $P_i$ is near $E$. Therefore, relative comparisons of host status must be made at constant $P_i$ and over a constant time interval. The designation of cultivars as good host, intermediate host, or poor host is relative, and depends on the shape of the relationship between $P_f$ and $P_i$.\[^{[5]}\]

### POPULATION DYNAMICS AND NEMATODE MANAGEMENT

Many agricultural practices are used to suppress nematode population levels.\[^{[2]}\] The use of crop rotation and cover crops for nematode management is based on the disruption of nematode population cycles. By understanding the relative degree of buildup or decline on various crops, an optimum crop sequence can be planned for minimizing nematode impact. The $P_f$ at the end of one crop becomes the $P_i$ for the next crop planted in the site, and so forth. Winter or fallow periods must be included as well.

Predators, parasites, and competitors all have the potential to affect nematode population dynamics and change the equilibrium density for a particular situation. When fungal parasites or other nematode antagonists are present, population densities of plant-parasitic nematodes stabilize to lower levels than those present in soils without antagonists or in soils from which antagonists have been removed.\[^{[7]}\]

A number of physical and chemical soil properties affect nematode dynamics to varying degrees. These include texture, pH, organic matter, salinity, aeration, bulk density, nutrient status, as well as moisture and temperature.\[^{[4]}\] Rainfall and soil type interact to determine soil moisture, which greatly affects nematode activity. Activity and population growth may cease or decline as soil conditions become too dry or too cool. Nematode population growth is directly related to temperature as well as time. Therefore, the use of heat units or degree days often provides a forecast of population growth more accurate than the use of time alone.\[^{[4]}\]

### FACTORS AFFECTING POPULATION DYNAMICS

A variety of biological factors affect nematode population dynamics. The genetics, degree of resistance, and resistance mechanisms available are essential features of the crop cultivar that affect its host status to nematodes. The responses of the same nematode species on the same crop cultivar may differ from place to place due to genetic and physiological variation among nematode populations. Recognized biotypes, races, or pathotypes are known in a number of important nematode genera including *Heterodera*, *Globodera*, and *Meloidogyne*.\[^{[6]}\] But even when biotypes are not recognized, isolates (populations from different sources) of the same species may respond differently in their virulence and population growth.
because they result in population decline \((P_f < P_i)\). Using this approach, simple models of crop sequences and nematode dynamics over time can be constructed.\(^4\) Models forecasting population dynamics are available for a number of plant-nematode systems.\(^4\)

With perennial crops, methods may be directed toward minimizing equilibrium densities of plant-parasitic nematode over time. This may be accomplished by use of resistant rootstocks, if available. The task is more difficult with susceptible perennials, but plant-parasitic nematode numbers in orchards of various fruit crops were suppressed or stabilized at relatively low levels when natural enemies were present.\(^7\) Efforts to conserve and enhance the naturally occurring antagonists that are common in agricultural soils have focused primarily on the use of appropriate organic amendments, tillage practices, and cover crops, but much remains to be learned in this area.\(^2,7\)

**CHALLENGES**

Measuring changes in nematode population levels and forecasting population growth over time requires sampling to determine \(P_i\) and other critical population estimates. The difficulty and variability involved in nematode sampling is well-known, and so estimates of \(P_i\) may be associated with substantial error. If \(P_i\) values measured with error are used in population dynamics equations and models, the error of the estimate may be magnified over time. Therefore, periodic sampling of nematode population densities in future crops and sequences is useful to be sure that forecast estimates are not drifting far from reality. Alternatively, a more complex and stochastic approach could be used, providing model output as probability distributions or ranges rather than mean population densities.\(^4\)

The greater limitation in applying population dynamics in nematode management is the relative lack of specific information on the dynamics of particular nematode species and isolates on specific crop cultivars. Furthermore, the nematode-host relationship varies with local agricultural practices and environmental conditions. This type of highly specific information is required to better anticipate nematode population changes and design appropriate management strategies.

**CONCLUSION**

Although deficiencies exist in our current knowledge of nematode population dynamics, new information is continually becoming available on nematode population response and host status on existing crop cultivars, new crop cultivars, and on potential and currently used rotation crops and cover crops. As concern over local variation in nematode isolates and dynamics increases, small on-site tests of host status and nematode buildup on candidate crop cultivars should become more frequent. As chemical nematicides become more limited, demand should increase for alternative practices such as resistant cultivars, rotation crops, cover crops, or allowing land to lie fallow. All of these alternative methods require a detailed understanding of nematode population dynamics to be used effectively.

Nematode Problems: Most Prevalent

Larry Duncan
University of Florida—IFAS, Lake Alfred, Florida, U.S.A.

INTRODUCTION

The phylum Nematoda (Nemata) comprises aquatic roundworms that occupy virtually all habitats on earth. Nematodes are the most numerous metazoans on earth and the phylum is one of the most species-diverse. It has been estimated that only 3% of a half-million species have been described. Nematodes are adapted to numerous life strategies with major trophic groups consisting of primary (plant parasites) and secondary consumers (bacterivores, fungivores, omnivores, predators, and animal parasites). They play a critical role in the fertility of agricultural soils as major contributors to nutrient decomposition in soil food webs, and their ubiquity makes them ideal organisms to study as biological indicators of soil processes. In contrast to the beneficial roles played by nematodes, all plant and animal species have nematode parasites. Parasitism of crop plants by some nematode species is of little economic significance, whereas others are among the most serious agricultural pests.

ECONOMIC IMPORTANCE

Crop losses due to nematodes vary by crop and region. Losses are difficult to estimate because plant-parasitic nematodes are microscopic soilborne organisms and damage frequently goes undetected. Most crop plants in a field are parasitized by several species of nematode, yet spatial patterns and population densities of damaging species are often poorly understood within fields and across regions. Average losses in the major food and forage crops worldwide have been estimated in the range of 11–14%. As for most pests, nematode damage to crops is greater in tropical than in temperate regions due to greater diversity and abundance of nematodes in the tropics. Average estimated losses to nematodes are also higher in less developed countries (13–17%) than in industrial countries (7–11%) due to a lack of management resources. For example, citrus yield loss to nematodes in Florida and California, where resistant rootstocks and nursery certification programs are used, do not exceed 5%, whereas average yield losses of 14% are reported from other regions of the tropics and subtropics.

SELECTED NEMATODE-CROP ASSOCIATIONS

Two classes, Secernentea and Adenophorea, are generally recognized in the Nematoda. The orders Tylenchida and Aphelenchida (Secernentea) contain plant-parasitic nematodes, as does the order Dorylaimida in the Adenophorea (Table 1). The mouthparts of all plant-parasitic nematodes are modified sclerotized structures known as stylets. The stylet functions much as a hypodermic needle, puncturing cells to secrete digestive enzymes and other chemicals into plant cells, and thereafter withdrawing cell contents (Fig. 1A). The generalized life cycle of these parasites is also similar, consisting of the egg, four juvenile stages, and the adult. However, feeding habits of plant-parasitic nematodes differ and are a means to categorize species based on general behavior.

Ectoparasites and Semi-Endoparasites

Genera such as Criconemella, Helicotylenchus, Rotylenchus, Hoplolaimus, and Tylenchorhynchus are found frequently in the rhizospheres of many types of plants. These nematodes remain in the soil or penetrate only partially into the root cortex as they feed on root epidermal or cortical cells. Frequently they produce no measurable effect on their plant hosts. However, species in these and other ecotoparasitic genera are major pests of some crops. Mesocriconema curvatum (part of a group known as ring nematodes) is the most frequently encountered plant-parasitic nematode in Florida citrus orchards where it is of no economic significance. The closely related Criconemella xenoplax causes severe root pruning of peach trees, increases susceptibility of trees to bacterial canker by Pseudomonas syringae, and results in the disease complex peach-tree short life. More than 1.5 million peach trees were killed by the disease in South Carolina in the decade 1990–99, and the nematode affects orchards throughout the southeastern United States and to a lesser extent in California. Hoplolaimus spp. (lance nematodes) parasitize a wide range of plants with little effect; however, Hoplolaimus galeatus damages turfgrass, corn, and cotton in the eastern United States, and Hoplolaimus columbus is an even more serious pathogen.

of cotton and soybean. Scutellonema bradys causes dry rot in stored yam tubers and causes major losses of this food staple in Africa, Asia, the Caribbean, and South America. Helicotylenchus spp. are among the most commonly encountered ectoparasitic nematodes worldwide, often in high numbers. There are few reports of significant damage by these nematodes with the exception of Helicotylenchus multicinctus on banana. The nematode is widespread throughout tropical America, Africa, the Middle East, and Asia, where it causes stunting, delayed fruit maturation, reduction of yield, plant topping, and shortening of the productive life of the plant. Stinging nematodes, Belonolaimus longicaudatus, are widespread in the southeastern United States and occur also in parts of the U.S. Midwest and California. In sandy soil, the nematode is highly pathogenic to a large number of agronomic and horticultural crops including cotton, potato, sweet potato, corn, turfgrass, strawberry, and citrus. The nematode can break resistance to Fusarium wilt in crops such as cotton. In addition to lesions in the root epidermis and cortex typical of feeding by ectoparasitic nematodes, stinging nematodes frequently feed at the root meristem where they may cause cessation of root growth (stubby root symptoms) and cell hypertrophy, resulting in swelling or small galls at the tips of roots (Fig. 1B).

The economic importance of ectoparasites in the Dorylaimida derives not only from direct damage to the plant root, but also from their ability to vector nepoviruses and tobaviruses responsible for numerous crop diseases (Table 2).[7] Species of Longidorus (needle nematodes) also cause direct damage and yield loss in crops such as corn, strawberry, tobacco, sugarbeet, lettuce, and celery. Xiphinema spp. (dagger nematodes) are widespread and cause serious damage to citrus, stone and pome fruit trees, forest tree seedlings, strawberry, and numerous other crops. Stubby root nematodes (Trichodorus spp. and Paratrichodorus spp.) are widespread in many crops including sugarbeet, in which they cause Docking disorder, and potato, where they increase the incidence of corky ringspot (tobacco rattle tobavirus). All dorylaimid plant-parasitic nematodes have feeding habits and cause symptoms similar to those of stinging nematodes. Effective nematode management can be more difficult to

Fig. 1 (A) Anterior end of Pratylenchus coffeae showing the stylet used to inject gland secretion into plant cells to withdraw cell contents; (B) Healthy citrus roots (left) and roots with stubby root symptoms (right) caused by feeding of Belonolaimus longicaudatus; (C) Migratory endoparasitic nematodes in root cortex; (D) Galls on roots caused by root knot nematodes. achieve for the dorylaimid species because reducing population numbers below levels that cause direct damage is often insufficient to prevent virus transmission.

**Migratory Endoparasites**

The most important groups of migratory endoparasitic nematodes are lesion nematodes (*Pratylenchus* spp.), burrowing nematodes (*Radopholus* spp.), and rice root nematodes (*Hirshmaniella* spp.). All life stages of the species in these groups are found within the roots of host plants where the nematodes migrate intercellularly (Fig. 1C). Secondary bacterial and fungal pathogens are important components of the damage resulting from lesions caused by migration of these nematodes. More than half of the world’s rice fields have been estimated to be infested by the tropical *Hirshmaniella* spp., with up to 25% yield losses. *Radopholus similis* is another tropical species with more than 250 known plant hosts. With the exception of Sigatoka disease, it is the most important pest of banana worldwide. The nematode is also a serious pest of coconut, tea, and spices such as black pepper, ginger, and turmeric. The citrus race of the nematode causes spreading decline disease of citrus in Florida, where yield reductions >50% are common in the absence of nematode management. The many *Pratylenchus* spp. also often have wide host ranges, with species adapted to both temperate and tropical climates. Species such as *Pratylenchus penetrans*, *Pratylenchus scribneri*, and *Pratylenchus neglectus* can damage a large number of tree fruit, vegetable, and field crops in temperate regions. An important interaction between *Verticillium dahliae* and *P. penetrans*, *P. scribneri*, or *Pratylenchus thornei* results in the potato early dying disease. *Pratylenchus coffeae* and closely related species are major parasites of coffee, tea, yam, banana, and numerous other major crops throughout the tropics.

**Sedentary Endoparasites and Semi-Endoparasites**

All of these forms require complex physiological responses by the host plant to initiate and maintain permanent feeding sites. Juvenile nematodes penetrate roots and transform vascular or cortical cells into permanent nutrient transfer cells. Most of the juveniles then develop into sessile adult females that assume a variety of nonvermiform shapes. Frequently, masses of eggs are produced in a gelatinous matrix, usually on the root surface.

The root knot nematodes (*Meloidogyne* spp.) are the most economically important nematodes, worldwide. With over 2000 known host species, relatively few crops are not susceptible to serious damage by one or more species of *Meloidogyne*. Infested plants are easily recognized by galls caused by hyperplasia and hypertrophy of cells adjacent to the feeding cells (Fig. 1D). Widely distributed species such as *Meloidogyne incognita*, *Meloidogyne javanica*, *Meloidogyne hapla*, *Meloidogyne
arenaria, and many others have broad host ranges on weeds and many field, vegetable, tuber, and ornamental crops. Fewer species (i.e., Meloidogyne coffeicola on coffee) are more limited in distribution and have few known hosts among crop species. In many crops (i.e., cotton and tomato), the incidence of Fusarium wilt and other soilborne diseases increase dramatically in association with root knot nematodes.

Host ranges of cyst nematodes (Globodera spp. and Heterodera spp.) tend to be narrow. An important adaptation by these nematodes is an ability of eggs to persist for long periods in the absence of hosts, protected within the body of the female, which forms a resistant cyst. Eggs hatch over a period of several years, and chemical cues from host plants stimulate eclosion of some species. The cyst also provides a very effective means of long-range dispersal by wind, through the alimentary process of birds, and on plant debris. Management of Globodera rostochiensis and Globodera pallida on potato in Europe and elsewhere has been an ongoing research goal for more than half a century. Heterodera glycines is well recognized for the remarkable speed with which it spreads to become a limiting factor in soybean growing regions where it has inadvertently been introduced. Heterodera trifolii (clover), Heterodera avenae (cereal), and Heterodera goettingiana (pea) are examples of other important species, as is Heterodera schachtii, which has an unusually wide host range (sugarbeet and other Chenopodiaceae as well as many Cruciferae).

Nacobbus aberrans (false root knot nematode) is endemic in the Americas where it has a wide host range and is an important pest of potato in South America, tomato in Central America, and sugarbeet in North America. Rotylenchulus reniformis (reniform nematode) is a warm/temperate climate nematode with worldwide distribution. It has a semi-endoparasitic habit; the anterior of the female is embedded deeply in the root while the posterior end and egg mass remain visible on the root surface. It can survive long periods and be transported by wind in a dehydrated condition (anhydrobiosis). It has more that 300 known host plants and is an economic problem on many vegetables, legumes, and cotton. In contrast, the host range of the semi-endoparasite Tylenchulus semipenetrans (citrus nematode) is limited to a few species of woody plants. It is ubiquitous in citrus industries throughout the world where it causes the disease slow decline.

Parasites of Aboveground Plant Parts

Ditylenchus dipsaci is a parasite of stems, leaves, or bulbs of onion, garlic, alfalfa, clover, and oat. Stems of infected plants are short and swollen, oat stems tiller prolifically, and infected bulbs of onion and garlic often rot in storage. Anguina tritici is known as the seed gall nematode. It transforms wheat and rye ovules into galls containing infective juveniles. Juveniles of A. tritici and D. dipsaci survive long periods (sometimes many years) between crops in an anhydrobiotic condition.

Aphelechnoides fragariae and Aphelechnoides besseyi cause serious losses in strawberry, in which they parasitize leaves and stems causing the disease spring crimp. When combined with the bacterium Rhodococcus fascians, A. fragariae causes cauliflower disease on strawberry. Aphelechnoides ritzenabosi induces interveinal necrotic lesions in chrysanthemum and other ornamental plants. Bursaphelenchus xylophilus causes the devastating pine wilt disease and Bursaphelenchus cocophilus causes red ring disease of coconut. Both of these nematodes are transported to new hosts by insect vectors.

MANAGEMENT: CURRENT PROBLEMS AND PROSPECTS

As with all plant pests, some characteristics of nematodes pose special challenges for devising effective management systems. Growers must make management decisions before planting, because there are no remedial options for many nematode problems. However, soil or plant samples must be processed by trained personnel to identify and quantify nematode infestations. As a result, nematodes are monitored less frequently than pests that are readily recognized in the field, and monitoring is beyond the means of farmers in developing countries. The effectiveness of crop rotation to reduce nematode numbers can be compromised by nematodes with wide ranges of crop hosts, or by communities of multiple species with different host ranges, or by nematodes adapted to survive for many years in the absence of a host. Host plant resistance is commercially available for some sedentary endoparasitic nematodes, but not for most other species. Resistance-breaking race development within genera such as Heterodera and species shifts in genera such as Globodera and Meloidogyne commonly occur. A trend toward discontinuation of pesticide-based management tactics due to environmental concerns will likely increase nematode-induced losses in some crops until appropriate alternatives are developed.

Ongoing research is focused on development of new sources of resistance, farming systems that employ cultural practices to reduce nematode numbers and help crops tolerate nematode parasitism, and biochemical/genetic approaches to a variety of management needs. Since 1997, a few genes responsible for host resistance to nematodes have been cloned and sequenced. Genes and gene products involved in nematode parasitism are being discovered that will provide new means to disrupt the nematode life cycle. Numerous nematode species have
been characterized using DNA-based methods that will eventually provide growers rapid and simple diagnostic tools to better manage these serious pests.

Nematodes and Host Resistance

Philip A. Roberts
University of California, Riverside, California, U.S.A.

INTRODUCTION

Host resistance to nematodes can be classified in several ways. First, it is important to recognize that parasitic nematodes have finite host ranges. Host plants are susceptible to nematode infection and allow the nematode to feed, develop, and reproduce, using the plant cells and tissues as a substrate. Some nematode species have broad host ranges that include hosts from many diverse plant taxa. Other nematode species, often the more specialized types, have narrow host ranges limited to one or a few plant families. Thus, nematodes do not parasitize all plants. The nonhost plants of a nematode are ones typically immune or resistant in the broadest sense, such that many attributes of the morphology, physiology, and biochemistry of the plant render it unsuitable as a host and prevent the nematode from feeding, developing, and reproducing.

Host resistance is more narrowly defined by its characteristic of being a heritable trait conferred by one or more genes that renders a host plant resistant. That is, the nematode is unable to feed, develop, and reproduce on the resistant plant to some measurable extent compared to a susceptible host plant. The importance of host resistance lies in its ability to protect the plant from full-scale infection, and in preventing the nematode from multiplying its populations. In agriculture and horticulture, resistance is considered a highly valuable character that, through genetic control in some plant-nematode interactions. A useful discussion of concepts of tolerance is given by Wallace. Resistance defined by mode of inheritance can be monogenic (single gene), oligogenic (a few genes), or polygenic (many genes). These genes may be major genes (large effects) or minor genes (small effects) for phenotypic expression. Other descriptions of resistance follow Vanderplank's classification of vertical resistance (race-specific or qualitative, differentiating intra-specific variants—races, pathotypes, or biotypes—of the pathogen) and horizontal resistance (race-nonspecific or quantitative, effective against all variants of the pathogen). Vertical resistance is usually simply inherited and conforms to a gene-for-gene type of plant-pathogen interaction. Horizontal resistance usually involves several genes with additive effects that express a quantitative

TERMS AND DEFINITIONS

Definitions of some important terms used in host resistance to nematodes are given here, and these have been described in detail in several reviews. Broader discussions of terminology for use in general plant pathology are also available. Fig. 1 provides a pictorial representation of some common terms. Most plants are immune or nonhost to most nematodes, blocking root invasion, nematode development and reproduction, and plant injury. For example, root-knot nematodes (Meloidogyne spp.) avoid roots of Royal Blenheim apricot, rendering the tree immune. ‘Resistance’ refers to the ability of a host plant to suppress development or reproduction of the nematode, and it can range from low to moderate (partial or intermediate) resistance, to high resistance. The term ‘resistance’ is also used to describe the capacity to suppress the disease, especially root-knot. Partially or moderately resistant plants allow some intermediate levels of nematode reproduction. ‘Susceptibility’ is used as the opposite of resistance. A susceptible plant allows normal nematode development to take place, as well as the expression of any associated disease (Fig. 1).

‘Tolerance’ and its opposite, ‘intolerance,’ are used to describe the ability of the plant to withstand the damage resulting from nematode infection. Tolerant plants grow well despite the presence of heavy infection, whereas intolerant plants are injured and grow less well or even die when infected (Fig. 1). Typically, resistant plants are also tolerant and most susceptible plants are injured to some extent by most nematodes. However, resistance and tolerance are not always linked, being under separate genetic control in some plant-nematode interactions. A useful discussion of concepts of tolerance is given by Wallace. Resistance defined by mode of inheritance can be monogenic (single gene), oligogenic (a few genes), or polygenic (many genes). These genes may be major genes (large effects) or minor genes (small effects) for phenotypic expression. Other descriptions of resistance follow Vanderplank's classification of vertical resistance (race-specific or qualitative, differentiating intra-specific variants—races, pathotypes, or biotypes—of the pathogen) and horizontal resistance (race-nonspecific or quantitative, effective against all variants of the pathogen). Vertical resistance is usually simply inherited and conforms to a gene-for-gene type of plant-pathogen interaction. Horizontal resistance usually involves several genes with additive effects that express a quantitative
level of resistance. In general, quantitative resistance tends to be less likely to “break down” due to selection pressure operating on the nematode parasite population.\(^\text{[9]}\)

Genes for virulence in the nematode match resistance genes in the host plant. Virulent nematodes are able to reproduce, whereas avirulent nematodes are unable to reproduce on a host carrying a specific resistance gene(s).\(^\text{[9]}\) The frequency of virulent individuals in nematode populations will determine the potential for selection of virulence in the presence of resistant host plants. In plant pathology, the genes encoding this trait are typically called avirulence or Avr genes. Nematologists sometimes refer to avirulence genes as genes for parasitism or parasitism genes, but these terms also have broader meanings.\(^\text{[2]}\)

Several terms have been used to categorize the variation within a nematode species based on differential responses to a host or resistance trait. Their use is somewhat confusing because of the indiscriminate use of them for different nematode groups. For example “race” or “host-race” has been used for categorizing variations within soybean cyst nematode (Heterodera glycines); “pathotype” has been used for potato cyst nematodes (Globodera pallida and Globodera rostochiensis) and for cereal cyst nematode (Heterodera avenae); and “biotype” for variations within the stem and bulb nematode (Ditylenchus dipsaci). Triantaphyllou\(^\text{[10]}\) offered the term “biotype” as a biological unit consisting of “a group of genetically closely related individuals sharing a common biological feature or phenotypic trait,” in this case parasitic ability on given differential hosts. Field populations may consist of individuals of different biotypes, and combinations of biotypes comprising field populations could be designated as races. An individual nematode may be assigned to more than one biotype, depending on the array of genes for avirulence that it possesses in relation to the genetic constitution of the host differentials used to classify the biotypes.\(^\text{[10]}\) Roberts\(^\text{[11]}\) adapted this biotype concept for categorizing variants within species of root-knot nematodes (Meloidogyne spp.) defined by reaction to resistance genes in different host plants.

### AVAILABILITY OF RESISTANCE

The current availability and use of resistant cultivars and rootstocks for nematode management is well documented.\(^\text{[1,4,9,12–14]}\) Success has been achieved in a significant range of crops for identification of resistance, followed by incorporation into commercially acceptable crop varieties and rootstocks and implementation in management programs. Even so, a large genetic resource of nematode resistance remains to be developed in many crops. Examples of highly successful developments in nematode resistance include the use of the Mi gene in tomato and the use of the Nemaguard rootstock for Prunus crops (plums, peaches, nectarines, and almonds), both used against root-knot nematodes, and the HI gene in potato, used against potato cyst nematodes. These resistance traits are used widely, but they do not protect against all populations and species of the target nematodes. Thus, there continues to be a concerted effort to find additional resistance traits in these crops.\(^\text{[9,14]}\) Technical advances in marker-assisted breeding, resistance-gene cloning, and plant transformation, and in bioengineering novel types of resistance to nematodes will undoubtedly expedite development of nematode resistant crops.\(^\text{[3]}\)

Plant resistance has been developed mainly to the highly specialized parasitic nematodes such as Globodera, Heterodera, Meloidogyne, Rotylenchulus, Tylenchulus, and Ditylenchus, which (except Ditylenchus) have a sedentary endoparasitic relationship with their host. The resistance may be effective against nematode species of different genera, against more than one species from the same genus, against a single species, or against certain populations of a species.\(^\text{[13]}\) Resistance to less specialized parasitic groups such as the migratory endoparasitic genera Aphelenchoides and Pratylenchus has been developed only in a few cases, and also to a few ectoparasitic nematodes, for example, to Xiphinema in grapevines.\(^\text{[15]}\) This pattern of resistance reflects the co-evolutionary forces between host and parasite, the more highly specialized relationships having resulted in specific genes for resistance and parasitism.\(^\text{[12]}\) The root-browsing ectoparasitic nematodes, with less specific feeding requirements, apparently have not been a strong selection force for resistance in plant hosts in most interactions, although useful differences in resistance do occur.\(^\text{[16]}\) Recently, the
potential for bioengineering novel forms of resistance based on molecular approaches has gained considerable attention and holds much promise, particularly as technologies advance to enable a more streamlined approach, and some progress has been made in developing novel root-knot nematode resistance.\[17\]

**EFFECTS OF RESISTANCE**

Resistance has two major attributes that contribute to its success in nematode management programs. These are the tolerance of most resistant plants to nematode infection, which imparts a ‘‘self-protection’’ characteristic to enhance growth and yield, and the suppression of nematode multiplication, which results in fewer nematodes in soil that could damage a following susceptible or intolerant crop planted in rotation.

**Protection of Yield Potential**

The impact of resistance and tolerance traits on crop yield can be quantified, and such knowledge can be used for predictive management approaches based on preplant sampling of nematode population densities in soil. The general relationship of relative yield to initial nematode density, called a damage function, has been defined according to the relative levels of resistance and tolerance and is depicted in Fig. 2\[12\]. For susceptible, intolerant crops, this relationship is linear except at very low or very high population densities. Both the position and the slope of the curve will be governed by the relative tolerance of the particular cultivar. The ideal genotype is one that combines high tolerance with high resistance. The main advantage of this yield protection is that in many cases, the resistant crop can be grown successfully without additional inputs of nematode control. For many crops, resistance and the associated tolerance eases or eliminates the reliance on chemical controls with soil-applied nematicides. In perennial vine, tree fruit, and nut crops, the primary objectives of incorporating nematode resistance into acceptable cultivars and rootstocks are improved yield and longevity, and the majority of forms of resistance in these crops also confer the required tolerance to infection to meet these objectives.\[14\]

**Suppression of Nematode Populations**

In annual cropping systems where from one to several crops per year may be grown on the same ground, nematode problems can be managed by including crops with different levels of resistance. Susceptible crops allow large increases in nematode populations, even from low initial population densities. The large population densities remaining after the susceptible crop often will be highly damaging to a following susceptible crop. Resistance, on the other hand, will suppress nematode multiplication to an extent determined by the level of resistance expressed in the plant. Resistance may be expressed at low, moderate, or high levels, and these expression levels will largely determine the nematode multiplication rate. Therefore, a susceptible crop planted after a highly resistant crop will be protected from nematode infection to a level that reduces or eliminates the need for additional nematode management inputs. These rotation benefits of nematode resistance have been demonstrated in several nematode-plant interactions in annual cropping systems, most notably for root-knot and cyst nematodes and their host crops.\[3\] In practice, the use of host plant resistance in combination with other control tactics is encouraged, because field research has shown that resistance can break down through selection of virulent nematode populations. An integrated management approach will tend to lower the selection pressure for virulence that may occur when resistance is used alone, thereby promoting the durability of the resistance.\[3,9\]

Nematodes: Ecology

Howard Ferris
University of California, Davis, California, U.S.A.

INTRODUCTION

Nematodes are among the most successful of multicellular organisms. They inhabit every environment imaginable. Although less diverse in number of species than some other phyla, they are incredibly abundant in number of individuals. An estimated four out of every five multicellular organisms on the planet are nematodes,\(^1\) surely a testament to their success and their ability to adapt physiologically and behaviorally to diverse habitats and niches. Cobb\(^2\) asserted that if all matter other than nematodes were removed, the outlines of geographic features, vegetation, and centers of habitation would be recognizable by the abundance and characteristics of nematode communities. That understanding has grown, and nematode community structure is now recognized as a powerful tool in the biomonitoring of soil history and condition.\(^3\) The ecology of plant and soil nematodes can be considered at several levels of resolution, for example, the physiological and behavioral response of individuals to environmental conditions; the reaction of life history traits to environmental resources, and the resulting consequences to abundance and spatial patterns; and the structural positions and functional roles of the organisms in the ecosystems that they inhabit.

PHYSIOLOGICAL ECOLOGY OF PLANT AND SOIL NEMATODES

Like all nematodes, those in plants and soil respond both physiologically and behaviorally to environmental conditions and cues. As poikilotherms, their metabolic activity is modified by temperature; the efficiency of energy release for cellular and organismal function approaches a maximum when they are exposed to favorable temperature ranges. Nematodes are aquatic organisms. In soil, they inhabit water surrounding soil particles, and their permeable cuticle provides direct contact with their microenvironment. They do not rapidly migrate from stressful conditions, and many species survive dehydration, freezing, or oxygen stress; others are more sensitive. Metabolic activity becomes constrained by limiting factors, including availability of moisture in the soil or plant material in which the nematodes live, or the availability of oxygen to drive metabolic processes. They are also affected physiologically by the osmotic condition and pH of the milieu. Such factors vary considerably as concentrations of the soil solution are affected by rainfall, percolation, and evapotranspiration. The amplitude of tolerance to such varying conditions determines the habitats occupied by different species.\(^4\)

It seems reasonable to assert that population levels or aggregations of nematodes in soil or plant material will be greatest where the integral affect of environmental conditions is optimal for their metabolism. In such locations they should feed more effectively, move most efficiently, reproduce most rapidly, and survive longest. Aggregations of nematodes are also enhanced by kinetic effects (movement). Movement is most rapid in favorable zones and less rapid, or even prevented, in unfavorable zones. Of course, the overriding determinant of population aggregates is the presence of food and the ability of nematodes to detect and access it while potentially constrained by the top-down effects of density-dependent predation by natural enemies.

BEHAVIORAL ECOLOGY OF PLANT AND SOIL NEMATODES

Nematodes respond to environmental (and other organismal) cues through taxes and kineses. Kineses are alterations in rate of activity; taxes are directional responses to stimuli. Chemosensory signals are detected by the amphids, which may be relatively small in environments where signal strength changes slowly (e.g., soil), or elaborate where signal strength is more dilute or changes rapidly (e.g., freshwater or marine environments). Even where amphids are small, as in most soil nematodes, expansions of the neuronal endings and the presence of mucoidal material may enhance their sensitivity. In those nematodes (e.g., *Caenorhabditis elegans*) where the nervous system has been studied intensively, cell bodies of amphidial neurons are aggregated in the nerve ring, which may allow some integration of signal strength from the amphids on either side of the head—or between amphids and the posterior phasmids—and allow generation of a signal for muscular responses.\(^5,6\)
Chemosensory communication between individuals is evident in taxis responses of males to females in sexually reproducing species and in the apparently tactile determination of the location of reproductive structures during mating. Response to host signals is generally strongest in plant-feeding nematodes that have a narrow host range and less obvious in those species with wide host ranges. Nevertheless, coordination of life history events with host availability is very important in species that have evolved sophisticated host–parasite relationships, for example, the root-knot nematodes, *Meloidogyne* spp. In those cases, the food reserves packaged into the egg by the female nematode must be sufficient to drive the embryo through several hundred cell divisions, a molting event from the first to the second juvenile stage, hatch from the egg, detection and migration to a host root, penetration of the root tissues through a complex migration pathway, and induction of a feeding site. All of those energy-intensive activities are necessary before the nematode is able to independently obtain new resources. Clearly, there are many opportunities for disaster, including inability to find a root, a nonhost response by the root, and insufficient residual energy to complete the penetration process.

**POPULATION ECOLOGY OF PLANT AND SOIL NEMATODES**

Population processes are, of course, regulated by physiological responses to the environment. The dynamics of increase and decrease in nematode populations are the integral of birth and death rates as constrained by environmental conditions, resource availability, and community regulatory pressures. Birth rates are affected by the intrinsic capacity of female nematodes to produce eggs and the duration of the life course over which those eggs are produced. Birth rates may be influenced by availability of males where fertilization is necessary, but not where parthenogenesis occurs. Hermaphroditism occurs in some bacterial-feeding nematodes (e.g., *C. elegans*). In those cases, the number of viable eggs produced is greater when cross- rather than self-fertilization occurs, apparently because the hermaphrodite does not produce and store enough sperm to fertilize all the eggs it is capable of producing.

Most plant and soil nematodes seem to produce eggs for the duration of their adult life course. Induced mutants of *C. elegans* may have extended survival beyond the reproductive period, with possible competitive consequences for food. The occurrence of such variants in nature is unknown and, arguably, there would be strong selection pressure against them, as there does not appear to be any social contribution to the population on the part of elderly nematodes.

The life course of plant and soil nematodes may be as short as a week in opportunistic bacterial-feeding species; is often in the 4–8 week range in plant-feeding species; but may be as long as several years in long-lived, large-bodied plant-feeders, predators, and omnivores inhabiting undisturbed and stable environments. The distribution of death expectancy around the mean life duration is generally not known except in some model systems.

Resource availability in an environment determines its carrying capacity for a nematode population. In closed systems, that carrying capacity may be fixed by the total amount of carbon available. But in dynamic systems, such as those generated by a growing plant that is continually fixing carbon, producing roots, and depositing and leaking materials into the rhizosphere, the carrying capacity changes with time. For a plant-feeding nematode species, there is a delicate balance between the amount of damage or pressure a successful parasite applies to the growth of its host plant and the rate and amount of food that the host can make available to the parasite. At higher starting population levels, the damage to the host may be so great that growth and development of the plant is impaired, total photosynthetic input is compromised, and the nematode population is limited to a lower level than it might have been if initial population pressure were lower.

**COMMUNITY ECOLOGY OF PLANT AND SOIL NEMATODES**

Nematodes in any environment are components of communities of organisms and, depending on their feeding habits and life history attributes, fit into their communities in various functional roles. The essential feature of a community is that the participating organisms are interdependent as food resources or interact in some way in the acquisition of resources.

The community of interacting soil organisms is sometimes known as the soil food web. The primary sources of carbon and energy from soil organisms stem from the photosynthetic activity of plants. The flow of carbon from plant material into the soil food web is influenced by nematodes in various ways. Some nematodes are herbivores that channel carbon and energy into the soil food web by direct herbivory on the plant. Others feed on fungi and bacteria and so constitute important bridges between primary decomposers of organic material and detritus and the balance of the food web. Still others are predators and omnivores consuming a range of higher soil organisms. These exert pressure on the abundance of their prey and potentially regulate or even suppress prey populations. Structure of the community is maintained as the integral of the population ecology of various taxa and the regulatory effects of predation across and within
trophic levels, but ultimately the size and activity of the food web must depend on the amount of carbon entering the soil. A major goal of sustainable production systems that are reliant on the functional roles of soil food webs is to increase carbon flow into the system through detrital channels while minimizing carbon flow resulting from herbivory (Fig. 1).

Besides predation, mechanisms of interaction at the community level include interspecies competition and mutualism. Certainly, nematodes with the same feeding habits compete for resources, but in some situations, competition is mitigated by adaptation of the nematodes to different environmental conditions. Predominance of species in the communities varies with their thermal adaptation; competition is reduced by spatial and seasonal variations in temperature and its diurnal amplitude.\[^{13}\]

One interesting example of mutualism in soil nematodes is exhibited by the so-called entomopathogenic nematodes. These bacterial-feeding nematodes transport mutualistic bacteria into the intestinal tract of insects. There the bacteria are released, which kills the insect and provides an abundance of food for the nematode.\[^{14}\]

Communities of organisms tend to be centered on sources of food. In the soil, such foci may occur at the interface of organic litter layers and the mineral layers of the soil. They also occur at the metabolically active parts of the root system, the root tips. Because of the multiplicity and dispersion of the various organic matter sources that drive the soil food web (Fig. 1), coupled with the physical heterogeneity of the soil environment, the soil community tends to exist in patches. It might be considered a metacommunity, a series of borderless communities with opportunities for migration of organisms among the patches, depending on their motility and sensory capabilities.

Both resource availability and predation pressure affect soil nematodes, and the interplay between these forces affects the dynamics of the participating populations. Bacterial-feeding nematodes may enter inactive “dauer” states, which allows them to conserve resources and, perhaps, renders them less accessible or attractive to predators. Nevertheless, the predators require food, and both they and the prey nematode populations must decline in the absence of resources entering the system.

**SUCCESS OF NEMATODE ECOLOGICAL STRATEGIES**

Nematodes are found in every habitat, from frozen tundra to hot springs, and from marine sediments to alpine peaks. They obtain sustenance from every form of fixed carbon imaginable, from algae and bacteria to humans. Recent classification systems recognize around 19 orders that constitute the phylum Nematoda. Plant-feeding species occur in three of those orders and are most prevalent in one, the Tylenchida. This relatively small sector of the phylum has developed strategies for feeding on perhaps every species of higher plant and for coexisting with other species on the same plant. Most species feed on root tissues and so avoid the dry conditions of the aboveground habitat, but some species have become behaviorally and physiologically adapted to feeding in stem, leaf, and seed tissues. Enormous diversity exists among root-feeding strategies, from root tip feeders to root hair piercers, and from migratory ectoparasites that withdraw contents of individual cells to sedentary endoparasites that elicit highly specialized feeding-site responses from the host.

INTRODUCTION

Crop diversification has been one of the promises for European agriculture in recent decades. As a result of surpluses in production of the major food crops, which have arisen from increased productivity in the 1970s and EU pricing policy in the 1980s,[1] alternative crops for nonfood markets have received substantial interest. Overproduction of traditional food crops (sugar beet, grain, and potatoes) in Europe resulted in increased competition and a decline in profitability. Reduction of EU subsidies and the threat of cheap imported products from low-wage countries prompted many farmers to abandon their businesses. Farmers would benefit from additional outlets, especially in novel, industrial nonfood applications. Attention has been given to new markets for existing crops as well as to developing novel crops. Research and development activities have been directed toward valorization of agricultural residues and product development for various “industrial” crops to produce specific seed oils, proteins, starches, carbohydrates, or cellulosic fiber.

AGRICULTURAL DIVERSIFICATION AS EU POLICY

In the specific framework RTD programs of the European Commission covering agriculture and fisheries (ECLAIR 1988–1993, 3rd framework 1991–1994 AIR, 4th framework 1994–1998 FAIR, and 5th framework 1998–2002 Quality of Life) a large number of precompetitive projects have been conducted during the last decade to address the various aspects of agricultural crop diversification. Substantial budgets of millions of euros have been spent to enhance the links of agriculture with industry and to encourage collaboration between the institutions from the various member states. Many of the EC-funded projects (with ≥50% EU contribution) have been selected to promote industrial participation in innovation to enhance the chances of success for project implementation.[2,3] In addition to the EU framework programs, specific developmental work for agricultural diversification also has been carried out on a national level.

The EU policy for sustainable development promotes the use of renewable resources for production of industrial products that currently are derived from petrochemical or mineral resources. The potential for agricultural production of a wide range of industrial feedstocks has been scrutinized as a source for composites, plastics, and polymers; resins and adhesives; building and insulation materials; energy and fuel feedstocks; paints, coatings, and dyestuffs; soaps, detergents, surfactants, lubricants and waxes; and agro-chemicals, pharmaceuticals, and cosmetics.

AGRO-INDUSTRIAL PRODUCTION CHAINS

A large number of new crops for European farming have been studied for the purpose of agro-industrial production, together with some obsolete crops that have long been neglected. Successful (re)introduction of agricultural raw materials for energy, “green” chemicals, and other nonfood uses requires addressing the whole agro-industrial production chain, from primary agricultural production to the perceptions of industrial end-users and consumers.

Generally, research and developmental work is directed at technical bottlenecks in product development. Successful market introduction, however, depends largely on the reliability of supplies and on added value for the consumer. Quality control and product standardization have been considered to overcome problems in the industrial use of renewable raw materials. Crops are a natural product, and intrinsic changes in quality between crops grown under different conditions introduce a certain degree of variability that has to be accounted for.

The production chain for renewable resources can be divided into three main links: agricultural primary production, crop processing, and utilization (see Table 1). Difficulties in the organization of integrated production chains (including storage and transport, marketing and sales) for innovative agro-industrial products have been identified as major constraints in the successful commercial introduction of novel (ecologically enhanced) products to the market. Despite the interdependency of the different links in the chain, the interests of the various
players may be divergent and counterproductive. The price and performance ratio of the products prevails in terms of competitiveness on the market, rather than in quality or ecological benefits.

Since ecological arguments are not decisive in getting industries or consumers to choose renewable products, legislative measures on the use of less-sustainable products favor the utilization of new crops.

**OILSEED CROPS**

A number of crops previously established as minor crops for production of fodder, such as rapeseed, have been considered as feedstock for biofuel (biodiesel) production or plant-oil-based surfactants. The increasing area of oil crops in the EU, e.g., sunflower (Helianthus annuus) (with a 1993 maximum of 3.3 million ha) and rapeseed (Brassica oleracea) (2.4 million ha in 1990 and over 3.0 million in 2000),[4] has also initiated a search for outlets by-products such as lecithin for cosmetics and fermentation substrates.

The reduction of volatile organic solvents in paints, coatings, and adhesives has enhanced the industrial demand for specific plant oils. Legislation restricts the use of those solvents for professional use in the EU, and alternative products are on the market. However, higher costs and reduced practical value still restrict the more common use of ecological products.

Research has been conducted for the breeding and agronomy of new oilseed crops such as meadow foam (Limnanthes alba), crambe (Crambe abyssinica), castor (Ricinus communis), and Dimorphotheca pluviales. The oils and their derived products have been evaluated for the production of pharmaceuticals, cosmetics, oleochemicals, lubricants, coatings, resins, and lacquers. The economic feasibility of primary production and industrial product development has been evaluated, but so far, available varieties have not been able to yield sufficient product to generate larger industrial interest. However, the primary production of crambe has been addressed to enhance its productivity.

Commercial interests in specialty oils containing unusual fatty acids, such as poly-unsaturated fatty acids and hydroxyl- or epoxy fatty acids, has inspired much work on alternative oil crops. Examples are lupin (Lupinus mutabilis, L. albus), jojoba (Simmondsia chinensis), and Stokesia sp., investigated for use in cosmetics, pharmaceuticals, and as lubricants; and false flax (Camelina sativa), caper spurge (Euphorbia lathyris, E. lagasca), and marigold (Calendula officinalis), studied because of their specialty fatty acids content for medicinal purposes, food, and a variety of nonfood uses as well.

**FIBER CROPS**

Automotive industries have been the driving force in developing cellulosic fiber production for (thermoplastic) composite car parts. Traditional fiber crops such as flax (Linum usitatissimum) and hemp (Cannabis sativa), but also crops new to Europe such as kenaf (Hibiscus cannabinus) and broom (Ginestra sp.), have been studied intensively for nontraditional end uses in compounds and fiber composites with numerous synthetic polymers.[5]

The breeding and agronomy of new hemp varieties has been studied to produce high-yield fiber and low Tetrahydrocannabinol (THC) content. Experimental fields of fiber hemp have been established in many EU countries and commercial production has been introduced at some locations. New fiber production technologies for specific industrial utilization have been studied. Some products
have entered the market successfully at a modest scale. Production of high quality fiber hemp for textile use so far has not been commercially successful.

One of the identified issues for sustainable developments and ecological building—apart from the energy conservation aspects—is the use of renewable resources as building materials. Fibreboards, panels, and insulation materials for building applications have been developed based on flax, hemp, miscanthus, or fibres derived from agro-residues (wheat straw, reeds, etc.). The production scale (and related costs) of established building materials is hindering extension of the market share for renewable building products.

The use of plant fibres as geotextiles in civil engineering and as horticultural substrates or biodegradable plant pots is increasingly receiving attention. The competing (synthetic or mineral) market products, however, hold a strong position.

Despite substantial research on the pulping of annual fibre crops and agro-residues, the contribution of non-wood pulp as raw material in European paper and board industries remains marginal. Some flax and hemp fibre is processed into specialty paper. Efforts to upgrade straw pulps for paper and board production have been unsuccessful, and the last straw-pulp mills have been closing in the EU.

Other fibre crops investigated for cultivation in various EU regions are Hibiscus esculentus, for making paper and reinforcing fiber, and for its nutritious pods; and domestications of stinging nettle (Urtica dioica), with potential as textile fibers.

Profitable EU agricultural production of nonfood crops implies competitiveness with cheaper raw materials produced from other regions. The availability of bulk quantities of fiber products like jute and sisal, and the potential large-scale production in Eastern Europe of flax or hemp is forcing EU agro-industrial production into a specialized niche market. Traditionally, flax fiber production in Western Europe for high-quality linen textiles has been able to cope with competing imported raw materials because of its high quality standard. The concentration of conventional linen promotion on the fashionable textile market in past decades has increased the dependency of the sector on a strongly fluctuating market segment. One way for EU agriculture to compete on the world market in lignocellulosic fibers is to supply high-quality raw materials with added value for the user. Only when the qualitative aspects of each specific end use have been defined in detail can this be achieved.

BIOMASS (ENERGY) CROPS

Promotion of the use of biomass for the production of ‘‘green’’ energy is one of the means to achieve a political target: to stop global warming and reduce CO₂ emission levels. Agricultural production of biomass crops for generation of bioenergy has received substantial attention in the EU. Elephant grass (Miscanthus sp.) especially has been selected for its potential high productivity and has been intensively studied agronomically to find suitable genotypes for different climatic regions. Breeding, propagation, planting, and harvesting technologies for Miscanthus have been the subject of study. Other perennial C₄ grasses such as sweet and fiber sorghum (Sorghum sp.) and giant reed (Arundo donax), which may be suitable for biomass production in the southern regions of the EU, have been evaluated. A production system for reed canary grass (Phalaris arundinacea) has been investigated in the more northern regions. More exotic species studied for Europe are switchgrass (Panicum virgatum) and bamboo (Phyllostachys sp.).

Because of the relatively low costs for fossil fuel and the lack of supportive political policy, dedicated agricultural production of new energy crops still remains questionable. Therefore, dual-crop-use options are being evaluated to increase the total added value. For example, the same crop might provide both energy and paper pulp, or composites, or building materials, or horticultural substrates.

Apart from the fast-growing grasses and tree species such as willow, poplar, and eucalypt, that have been promoted for paper pulp or biofuel production, another high-yielding perennial, cardoon (Cynara cardunculus), has been investigated for growing on marginal and set-aside lands in arid areas of southern Europe.

The work on biofuel utilization has been focusing on thermal conversion by burning, gasification, and pyrolysis of biomass. However, the costs of energy production remain a critical component in the development. For the production of liquid fuel, laboratory-scale hydrolysis/fermentation experiments have been conducted to produce ethanol, ABE (acetone, butanol, ethanol), and hydrogen gas from lignocellulosic feedstock.

CARBOHYDRATE CROPS (CEREALS AND TUBERS)

Innovation and industrial product development for established crops such as cereals, sugar beets, and potatoes would offer the advantage of known agricultural production. Possible uses as feedstock for bioethanol fuel production have remained at the R&D stage due to the economics of production and political factors (bioethanol production would become competitive only when crude oil sells at $30–40 per barrel). Other biotechnological methods to valorize agricultural waste products, such as sugar beet pulp or wheat and maize bran, have been investigated in detail, for example, for the production of vanillin.
Much research effort by various groups has been directed into the production and processing of biodegradable plastics based on thermoplastic starches from potato, corn, and other cereals. Biodegradable plastics for packaging and single-use items are being produced on industrial scale, but so far no breakthrough has been accomplished to generate a wider market share.

A production area of 15,000 ha of chicory (Chicorium intybus) for inulin production has been established, concentrated in Belgium, France, and the Netherlands. Inulin and fructan for nonfood applications are under investigation.

“GREEN” CHEMICALS AND PHYTOPHARMACEUTICALS

Higher-value-added specialty chemicals that can be derived from plant sources have been investigated for use in textiles, cosmetics, flavors, fragrances, and pharmaceuticals. Some examples:

- Reintroduction of traditional dye plants such as woad (Isatis tinctoria), madder (Rubia tinctorum), weld (Reseda luteola), and goldenrod (Solidago sp.) has been attempted by improving the harvesting and extraction technologies. On a modest scale, some production has been realized in Germany.
- Caraway (Carum carvi) has been introduced as a crop for the production of carvon, which has been demonstrated to have sprout-suppressing properties in potato storing.
- Some research on guayule (Parthenium argentatum) as a source for nonallergenic natural rubber production has been conducted.
- Agricultural production of Stevia rebaudiana as a promising new crop for southern regions of the EU has been studied, both for its sweetener properties and for nonfood uses.
- Glucomannan from konjac (Armorphophallus sp.) has been studied for its use as a texturing agent in food and nonfood applications.
- The tuber and seeds of ahipa (Pachyrhizus ahipa) have been evaluated for their specific (glyco)protein content and biocidal action.

WHOLE CROP UTILIZATION

Since it has been concluded that primary production of many crops is not economically feasible to produce only one principal component, valorization of residues from the crop has been considered. Many crops grown for fiber also may yield a useful oil (or the other way around) and produce other biomass residues (stalks, shives) that could tip the overall economic balance.

Bulk quantities of biomass with reduced (or negative) costs are available from many sources. For example, large quantities of verge grasses are being produced annually from roadsides, and many residues from agricultural and horticultural production accumulate without further use. Utilization of these residues for energy production would make a cheaper feedstock, but for a useful fuel preprocesing is a prerequisite. Green tissues are generally richer in water, protein, and minerals, which could cause more difficulties in thermal conversion.

CONCLUSION

Despite the scope for new outlets and prospects for sustainable production of renewable raw materials, the acceptance of new crops at the farm level, in industry, and in the market has been complicated because of the adapted machinery and investments required at the various production levels. Much has been achieved over the last decade in exploration of the potential markets for different new industrial crops, although a real breakthrough still has to come. As a renewable raw material, crops do present strong marketing arguments as “eco-efficient” products for the development of sustainable consumption and production. Diversification of the market for renewable raw materials in the automotive industry, building and construction materials, paper and pulp, bioenergy, geotextiles, etc., are all in the picture if: 1) quality control of the agro-industrial production chain can be organized according to ISO standards; and 2) supplies of specified products to industrial buyers can be guaranteed.

Concerted action by the whole agro-industrial production chain will be necessary to attain the targets of sustainable consumption and ecologically safe production of the whole range of renewable products.

New Secondary Metabolites: Potential Evolution

David R. Gang
University of Arizona, Tucson, Arizona, U.S.A.

INTRODUCTION

When we consider the potential within the plant kingdom to evolve new metabolites, we need to consider two important properties of plants. The first is the diversity of building blocks—of current metabolites—found in plants, and the ability of these building blocks to be put together in new ways to produce new metabolites. The second important property to consider is the biosynthetic machinery within a plant that is responsible for producing metabolites, and the ability of this machinery to be modified so that new metabolite transformations are possible.

PLANT METABOLITE STRUCTURE AND DIVERSITY

Plants produce an amazing array of metabolites with very divergent structures and functions. These metabolites result from the action of several important and diverse biosynthetic pathways. Beyond the primary metabolic pathways—such as glycolysis, gluconeogenesis, and amino acid biosynthesis—the most significant metabolic pathways in plants are the terpenoid pathway (over 30,000 compounds identified), the phenylpropanoid pathway (over 5000 compounds), and the alkaloid pathways (over 12,000 compounds). Over 50,000 such metabolites have been identified in the plant kingdom, and in the whole of nature there may be several hundred thousand or more of such compounds.

Examples of this structural and functional difference are shown in Fig. 1. These molecules (eugenol, curcumin, or indole glucosinolate) can have simple structures, or they can be much more complex, (salvianin, vinblastine, or taxol). Plant secondary metabolites (also called specialized metabolites or natural products) may be the best manifestation of biodiversity within the plant kingdom, and in the whole of nature there may be several hundred thousand or more of such compounds.

BIOSYNTHESIS OF PLANT METABOLITES

The majority of plant metabolites are constructed in a manner whereby a basic structural motif is first synthesized and defines a new set or class of compounds. This core molecule is then further modified, often leading to great structural diversity within members of its compound class. This is what happens in the production of the anthocyanins, which are produced by a branch of the flavonoid pathway (Fig. 2). In the flavonoid pathway, a number of structural classes are formed (indicated by parentheses in Fig. 2). These classes serve as core building blocks for production of more elaborate molecules (e.g., salvianin).

The vast majority of chemical reactions involved in the production of plant metabolites are catalyzed by enzymes that are part of specific biosynthetic pathways. For example, a number of steps are known in the pathway that leads to the formation of salvianin in scarlet sage (Fig. 2). All of these appear to be catalyzed by enzymes: 1) polyketide synthases; 2) isomerases; 3) hydroxylases (cytochromes P450); 4) NADP⁺-dependent dehydrogenases; 5) dehydratases; 6) glycosyltransferases; and 7) acyl-CoA-dependent acyltransferases. Even though the reaction converting the chalcone to the flavanone can occur spontaneously, this reaction is nevertheless catalyzed by an enzyme. Many other enzyme classes and reaction types are involved in the formation of other plant metabolites, but this example clearly shows that many different classes of enzymes are involved in the formation of any given metabolite that accumulates in a given plant. The genes encoding these enzymes are the genetic material in the plant kingdom that can be modified through evolutionary processes to produce new enzymes that in turn can produce new metabolites.

Encyclopedia of Plant and Crop Science

turn catalyze the formation of new metabolites.\textsuperscript{2,4} The ability to produce new enzymes is the key to the ability of plants to evolve new metabolites.

**EVOLUTION OF NEW ENZYMES AND PATHWAYS**

Several processes occur in plants that may lead to the formation of new enzymes. These range from polyploidization events and whole genome evolution, to gene duplication and divergence, and allel divergence.

Polyploidization events have been a common phenomenon in plant evolutionary history.\textsuperscript{5} These events lead to the merging of whole genomes from two distinct species. When this latter process occurs, large amounts of DNA can be lost or rearranged. This leads to formation of new chimera chromosomes.\textsuperscript{5} As can be imagined, this can lead to the duplication of some sets of genes. This sometimes occurs with the concomitant loss of other sets of genes. Only those losses that are not detrimental to the plant’s survival will lead to viable progeny. Thus, it is possible that whole groups of biosynthetic enzymes and the resulting pathways and metabolites may be lost, so long as these metabolites are not absolutely required for survival of the plants. In addition to the process of polyploidization, it is possible that segments of chromosomes may be duplicated by other processes. These duplications may be large or small. As a result of all of these processes, the newly duplicated genes become redundant. This sets the stage for the evolution of new functions.

Once duplicate genes are formed, only one copy need retain the original activity for the plant to continue to make the same set of metabolites. The other copy is free to be mutated—to evolve. Many processes may be involved in this evolution. The new gene could simply accumulate random mutations, possibly leading to an altered substrate-binding cavity and new enzyme specificities. The
results of this process have been observed in the production of a group of phenylpropanoid compounds in sweet basil. In this case, two very similar enzymes (90% identical at the amino acid level) have been found that possess different substrate preferences. The difference in activity is the result of mutation of a single nucleotide in the gene sequence, which led to incorporation of a different amino acid in the active site of the enzyme, and thus to altered enzyme function. In this case, the original enzyme was from a secondary metabolic pathway. Another example of divergence of duplicated genes is the evolution of homospermidine synthase, which is found sporadically in a number of unrelated plant families. This enzyme has very high homology to deoxyhypusine synthase, which is involved in activation of eukaryotic initiation factor 5A (eIF5A). eIF5A is required for proper cell growth. Thus, formation of new enzymatic functions in plant secondary metabolism can be derived directly from enzymes duplicated from primary metabolism.

Other examples of divergence after duplication are found in plant glycosyltransferases, polyketide synthases, cytochrome P450s, and many other enzyme classes. In fact, for some of these enzyme types, there are dozens to hundreds of
individual members in a given plant’s genome. For example, there are over 250 different cytochromes P450, over 360 glycosyltransferases, over 60 acyltransferases, and over 50 dehydrogenases in Arabidopsis alone. This plant produces only a limited number of secondary metabolites. The function of only a small handful of the genes in these large gene families is known. The diversity in extant enzymes in these classes in the plant kingdom as a whole must be significantly larger.

CONCLUSION

Given the great number of extant metabolites in plants, a great pool of structural building blocks can be modified by future evolution in plants. In addition, a large pool of enzymes in any given plant—many of which are duplicates and redundant—are available for transformation into new enzymes via mutation and other evolutionary processes. Thus, because of the existing complex matrix of metabolites and enzymes in the plant kingdom, there is great potential for the evolution of new enzymes, new pathways, and new metabolites. Advances in genomics, proteomics, and metabolomics allow this area to be investigated in a manner not previously possible.

INTRODUCTION

The availability of water and nitrogen are considered to be the two major factors controlling plant growth and crop yield. In the past, the application of large amounts of nitrogen fertilizer by farmers has been a common practice. However, concern has been raised over the leaching of nitrogen from the soil, which can contaminate drinking water, cause toxic algal blooms, and thus affect human health, commerce, and tourism. There is now a strong move to adjust nitrogen input according to the nitrogen requirement of the plant and corresponding to the target yield.

USING NITROGEN TO OBTAIN HIGH CROP YIELDS

The yield of a high-quality wheat crop grown in Western Europe can reach 10 metric ton hectares (ha$^{-1}$). In addition, an equivalent amount of straw is produced, with an average 1.5% N in the dry matter, representing a nitrogen (N) requirement of 300 kg ha$^{-1}$. A grass crop used for animal fodder may produce 20 ton ha$^{-1}$ but will contain 4% N, thus representing a N requirement of 800 kg ha$^{-1}$.[1] It therefore follows that in order to obtain these high yields, farmers need to apply large amounts of N fertilizers. The global use of N fertilizers has increased dramatically in the last 50 years and has now stabilized in the region of 80 million tons per annum. Nitrogen may be applied to crops in the form of ammonium (NH$_4^+$) or nitrate (NO$_3^-$) ions (often both together), urea, or as organic fertilizers derived from farmyard manure. In addition, legume crops are able to fix N$_2$ directly from the atmosphere through the utilization of symbiotic bacterial species in the root nodules. In well aerated neutral soils, the majority of the N is converted to nitrate. However, in acidic and/or anaerobic soils (e.g., in forests or for rice), ammonium ions are the major form of available N. The use of N fertilizers and the subsequent metabolism of the nitrogen-containing compounds within the plant are covered in two recent books edited by Bacon[2] and Lea and Morot-Gaudry[3] and in a special issue of the Journal of Experimental Botany.[4]

Unfortunately, the uptake of N by the crop plant seldom exceeds 60% of that applied. This loss of fertilized N can be due to leaching, erosion, runoff, or by gaseous emissions. The leaching of 20–30 kg ha$^{-1}$ can increase the nitrate concentration in the groundwater to above the threshold stipulated by the European Union (EU) for drinking water of 50 mg l$^{-1}$. Nitrogen may be lost to the atmosphere as NH$_3$ or following denitrification as N$_2$ or intermediate oxides, e.g., N$_2$O, NO, and NO$_2$. In addition, N may be sequestered by soil microorganisms in an organic form, which may then be available for subsequent crops.[5]

BIOMASS AND NITROGEN

The relationship between biomass production and the amount of N applied to the soil has been determined in a large number of field trials for most economically important crop plants. The generalized response curve shown in Fig. 1 clearly demonstrates that when there is a shortage of available N, productivity is very low. However, biomass production increases linearly with the supply of N until the asymptote is reached, at which point additional nitrogen does not increase productivity, and productivity is then limited by genetic potential. If growth is related to the N accumulated by the crop, then the initial slope, which is the true or intrinsic efficiency of nitrogen use by the plant, is steeper (more biomass per unit of N) than if related to the amount of N applied. The difference is a measure of the efficiency with which nitrogen is used, as is the difference between the point at which the plateau for biomass production is reached, when expressed per unit of absorbed and applied N.[6]

An abundant nitrogen supply increases the number of meristems produced by plants, thus encouraging branch and tiller formation and hence growth in most plants. In cereals and grasses the increased production of tillers gives rise to increased biomass and increased numbers of ears in grain-producing plants. As a consequence of the increased N supply, the leaf area index (leaf area/ground area, LAI) increases considerably. In a well watered winter wheat crop receiving 300 kg ha$^{-1}$N grown in Europe, the LAI can reach 6 by June. However, in a crop receiving only 75 kg ha$^{-1}$ N, the LAI may only reach 2, with values below 1 reported in crops receiving no nitrogen at all.[11] The light energy received by the crop is
used by the leaves to assimilate CO₂ in photosynthesis and also to carry out a range of other synthetic reactions. In fact it has been calculated that 20% of the N in the leaf of a C₃ plant is contained in light-harvesting pigments and proteins, 35% of the N is in the enzymes of the Calvin cycle including RuBP carboxylase/oxygenase (which is the major single component), and a further 20% is in other biosynthetic enzymes.⁷ Thus the addition of nitrogen not only stimulates the formation of new leaves to intercept all the light available (a LAI of >4 is required), but also raises the amount of enzyme protein available to carry out photosynthesis. Ultimately during leaf senescence, N is mobilized from the enzyme proteins and transported to the seed for incorporation into storage protein.⁷

A range of models of crop growth is currently available based on the concentration of N within a plant. These models utilize the terms %Nₘₐₓ, which is the maximum concentration of nitrogen that can be accumulated by the plant, and %Nₘᵦᵣₗ, which is the minimum concentration of nitrogen below which the plant cannot survive. These values can be obtained from field trials with increasing applications of N fertilizer. The critical value for N concentration %Nₗᵦᵣₗ lies between %Nₘₐₓ and %Nₘᵦᵣₗ and corresponds to the concentration of nitrogen, which permits maximal crop growth. Thus crops that are grown in conditions below %Nₗᵦᵣₗ suffer N deficiency and reduced growth, whereas plants that are grown above %Nₗᵦᵣₗ are able to store N. A discussion of the value of the various models available to establish %Nₗᵦᵣₗ has been recently provided by Jeuffroy et al.⁸

**VARIABILITY IN NITROGEN UPTAKE**

The nitrogen uptake by field crops is highly variable within a single year, between years, between sites, and with different crops even when the N supply is plentiful. This is partly due to the fact that the increase in crop N content with crop mass is not linear. Additional N uptake per unit of additional biomass declines as the crop gets bigger. A plot of %Nₗᵦᵣₗ against biomass provides a gentle downward curve and has been carried out for a range of plant species. C₄ species (e.g., maize and sorghum) were found to have a lower %Nₗᵦᵣₗ-biomass curve than C₃ species (e.g., wheat, rape, and pea), presumably due to the lower content of photosynthetic proteins within the leaf. The curves of a wide range of C₃ species, however, exhibit a remarkable similarity.⁹

**CONCLUSION**

There is a need to adjust the amount and timing of N application to crops to ensure that the maximum growth rate is obtained, while at the same time preventing wastage and hence possible pollution. As earlier, if the
actual N content of the crop falls below the critical N content there is a reduction in the growth rate. A small decrease in the uptake of N by wheat could cause a reduction in the grain N content from 11.5% to 10.5%, thus preventing its use for bread making. Thus methods have been developed to establish the N content of the crop, which preclude the use of complex and expensive analyses. Simple colorimetric tests for the concentration of nitrate in leaves are now available, which may be used in conjunction with an analysis of chlorophyll concentration using handheld photometers. Such techniques give a clear result and may be carried out rapidly in the field with a large number of samples.6

Nonchemical Weed Control: New Directions

Bo Melander
Danish Institute of Agricultural Sciences, Slagelse, Denmark

INTRODUCTION

Nonchemical weed control involves a wide range of methods and tactics used to control weeds without any support from herbicides. Mechanical and thermal methods, including mulching with dead or living mulches, are currently the most common nonchemical methods for direct use in crops. These methods are most often applied as part of a strategy that also involves cultural factors such as fertilizer placement, stale seedbed techniques (repeated soil cultivation prior to planting), and competitive crop varieties. Besides improving existing methods and weed control strategies, recent research has been oriented toward the development of high-technology solutions such as automatic steering systems for steereage hoes, global positioning system (GPS) for electronic mapping of crop seed positions for subsequent guidance of selective weeding devices, and computer vision for identification of crop and weed seedlings to guide highly accurate devices for physical targeting of weed seedlings. Band steaming prior to crop sowing is another area of interest for row crops with dense intrarow crop stands, where spacing is too limited for automatic and selective guidance of weeding tools.

WHY NONCHEMICAL WEED CONTROL?

Research on methods for nonchemical weed control in agriculture and horticulture has steadily increased up to the 1990s in many European countries, notably Sweden, The Netherlands, Germany, Italy, UK, Switzerland, and Denmark, mainly as a consequence of an increasing concern about herbicide usage among European populations. Both ground water and surface water have been unacceptably polluted in many cases owing to intensive pesticide usage, especially in The Netherlands and Denmark. Herbicides have often been the main reason for those contaminations; moreover, they may contribute significantly to a general impoverishment of the flora and fauna in agricultural landscape. Governmental actions have been taken in countries such as Denmark, Sweden, and The Netherlands to impose legislated directives to cut pesticide usage significantly. Similar concerns and subsequent actions also can be found in some states and provinces in the United States and Canada.

Other factors driving interest in nonchemical weed control are: the development of herbicide resistance, health risks for humans exposed to chemicals, and an increasing conversion to organic farming in several European countries, favorably subsidized by some European governments.

CURRENT NONCHEMICAL METHODS

Mechanical weed control methods are the most common nonchemical methods used in practice, and a wide range of implements is available for agricultural and horticultural crops. They are considered low-technology solutions with relatively low purchase and operation costs. The weeding mechanism of mechanical tools is mainly by uprooting and/or burying the weeds. Interrow cultivators, such as ordinary hoes with hoe blades mounted on either S-tines or shanks, rotary hoes, rolling cultivators, or power take-off (PTO)-driven cultivators, are used worldwide for controlling weeds growing between the rows (interrow weeds) in row crops such as maize, sugar beets, sorghum, potatoes, and many vegetables. The weeds growing in the crop rows (intrarow weeds) are better controlled by other mechanical means such as weed harrowing, torsion weeding, brush weeding, and finger weeding (images in Ref. [4]). However, mechanical intrarow weed control generally operates with low selectivity whether in cereals grown at narrow row spacing, or in typical row crops at wider row spacing. Low selectivity means that a high weed control level might be associated with severe crop damage, particularly if large weeds are to be controlled satisfactorily in a weakly anchored crop.

Flame weeding prior to crop emergence has been the predominant thermal weed control method in slowly establishing row crops such as direct-sown onions, leeks, carrots, and maize. There are two fundamental types of thermal weeders on the market: the covered flamers, flaming to 1900°C, or the infrared weeder, with essentially no visible flame and heating to 900°C. Both use liquefied petroleum gas or propane/butane mixtures as fuel. Flaming kills weeds that have emerged prior to the crop, mainly by rupturing the cell membranes causing the
indirect effect of subsequent desiccation. Hot water, hot foam, and vapor jet systems are other thermal methods that are used to control aboveground vegetation on hard surfaces, along roadsides, and in orchards and nurseries. These methods involve no fire risk, but fossil energy consumption can be very high.

Mulching with materials such as plastics, fibers, straws, and wood debris can be used in orchards, nurseries, and some vegetables. Light is excluded and the mulches constitute a physical barrier through which weed growth is strongly prevented. Mulches may provide complete weed control over long periods but are quite laborious to handle. The term “living mulches” covers a wide range of agronomic systems, but basically a living mulch acts as a cover crop. A cover crop is a secondary crop that is grown to suppress weed growth. It can be planted either before, with, after, or later than the main crop, depending on the purpose and tolerance of the main crop.

**IMPROVEMENTS OF EXISTING METHODS**

Recently, research has been conducted to better understand the mechanisms behind the killing effect of mechanical weeding principles to improve implements.[2] A number of investigations have focused on the tactical use of mechanical and thermal methods, and how they can be combined with cultural methods that mainly improve crop competitiveness and crop tolerance to withstand physical impact from weeding tools. Some promising weed control strategies in spring barley, onion, and pulse have been achieved from this work.[7] Results with mechanical weed control have been particularly good in transplanted row crops, where transplantation itself creates very favorable conditions for mechanical weeding because large crop plants are established in a newly cultivated soil. However, current techniques for transplantation are only profitable in some highly valuable vegetable crops and need to be further developed to become cost-effective in other row crops.

**NEW DIRECTIONS**

Within the last 5 years, three new steering systems have been developed and commercialized for hoes and other implements, where accurate steering along a crop row is required.[8,9] The systems are based on image analyses and have been developed for automatic steering with no need for an extra person to steer the implements (Fig. 1). The manufacturers claim a steering precision down to ±15 mm deviation from a center line at a driving speed of up to 10 km/hr. However, an experimental verification of those claims still remains to be seen for a number of crops and field situations such as sloping fields, different crop leaf architectures and growth habits, and poor crop stands blurring the row structure.

The new steering technology could be the first step in the development of more advanced image analysis systems able to distinguish crop plants from weed plants. This could be a breakthrough for the development of a robot weeder for row crops. Research in Europe is focusing on the possibilities of developing sensors or cameras that might handle such a task.[10] One of the visions is to develop an implement that can remove weeds selectively using a cutting device based on either laser technology[11] (Fig. 2), water jet systems, or mechanical cutters.

So far, the prospects of robotic weeding have only been studied in situations with abundant spacing among clearly visible crop plants such as Christmas tree plantations[12] and transplanted cauliflowers.[13] Requirements for a robotic weeder to operate with high accuracy and speed become crucial in poorly competitive row crops with...
limited spacing between individual crop plants. Research has shown that the closer to individual sugar beet plants the weed plants grow, the more they suppress the beet plants and thus have to be removed to preserve yield. To further increase accuracy and reliability of robotic weeding under such difficult circumstances, new research is focusing at the prospects of using electronic crop seed mapping to assist subsequent computer vision for identification of crop and weed seedlings.\(^{[14]}\) Crop seed positioning at sowing uses the technology of real-time kinematics GPS to create an electronic field map with geographical coordinates for each individual crop seed.

Soil steaming has acquired additional interest, realizing that the potential for robotic weeding in row crops with very dense intrarow crop stands (e.g., carrots and direct-sown onion and leek) appears to be very limited. Soil steaming prior to crop sowing can eliminate weed seedling emergence in the crop row by killing viable weed seeds in the heated soil volume provided that a maximum soil temperature of 70–80°C or more can be reached. A major goal is to develop an applicable technique for applying steam in bands corresponding to the intrarow area of a row crop, typically bands of 70–80 mm width and 50–60 mm soil depth.\(^{[15]}\) Band steaming is expected to use much less energy compared with current steaming techniques for arable usage, where the entire surface is treated down to 100–150 mm soil depth.

**CONCLUSION**

Research in nonchemical weed control methods has gained a renewed interest up to the 1990s in many western countries because of increasing environmental concerns. Several nonchemical methods have been introduced and studied in more detail, some of which are new principles, whereas others are old principles that have been subjected to new research. Some methods have become true alternatives to herbicides both in terms of effectiveness and economic feasibility, whereas others only have interest for organic cropping. New high-technology solutions have become increasingly important in recent years and several research projects are now looking at the potential of high technology to improve physical weed control methods.

Non-Infectious Seed Disorders

H. K. Manandhar
Nepal Agricultural Research Council, Khumaltar, Lalitpur, Nepal
S. B. Mathur
Danish Government Institute of Seed Pathology for Developing Countries, Copenhagen, Denmark

INTRODUCTION

Noninfectious seed disorders are nonpathogenic and nontransmissible unless genetically controlled. The disorders can be genetic, physiogenic, or caused by injuries. The genetic disorders are usually inherited and transmitted through seeds from one generation to another. The physiogenic disorders are mainly due to environmental conditions, nutrient deficiencies, and aging. In some cases, aging may be genetically controlled and also environmentally influenced. The injuries can be mechanical, chemical, or the result of insect damage.

Seed disorders can be visible or invisible. Visible disorders include cracking or splitting in seed coat; shrunken or wrinkled seeds; discolored seeds; and seeds with holes, abnormal shape, and reduced size. The invisible seed disorders include some genetic disorders, embryoless or embryo-damaged seeds, aging, and some micro-nutrient deficiencies.

Seed disorders can affect seed germination or produce weak seedlings and plants with symptoms of different kinds. Books such as Seed Pathology by P. Neergaard and Principles of Seed Pathology by V. K. Agarwal and J. B. Sinclair provide reviews on noninfectious seed disorders. An Annotated List of Seed-borne Diseases by M. J. Richardson also provides some relevant information on the topic.

VISIBLE SEED DISORDERS

Seed Coat Cracking or Splitting

This is one of the most common types of seed disorders. It can be either genetic or caused by mechanical injuries or environmental effects. Seed coat cracking due to genetic effects is common in eggplant, pepper, and tomato. Seed coat splitting occurs in flax and is more common in yellow-seeded cultivars. Similar disorder is also found in some cultivars of bean.

Mechanical injuries during harvesting, threshing, processing, and postharvest handling may result in seed coat splitting or cracking of many crops. Seeds with low moisture content and thinner seed coat have a higher chance of such damage. Machines with high-cylinder speeds result in damaged seed coats.

Desiccation of seeds during maturation results in cracking of soybean seed coat. Seeds harvested with high moisture and then stacked result in softening or cracking of seed coats.

The major concern over such seed coat abnormality is that it provides entry points for various types of organisms, pathogens, and saprophytes (Fig. 1). Entry of saprophytes is important because such organisms multiply under bad storage conditions (improper ventilation, high temperatures, high humidity). The effect is pronounced when seeds are stored at high seed moisture.

Discolored Seeds

Seed discoloration is often associated with environmental factors and nutritional deficiencies. Cold-damaged canola seeds become brown (see also shrunken seeds, discussed later). Frost-injured peanut seeds are off-white, water soaked or translucent, and off-flavor. Severely damaged seeds can only be used for oil stock. Under humid conditions, radish seeds develop a gray discoloration due to swelling of the subepidermal parenchyma, which results in distortion or cracking of the epidermis. This facilitates invasion by fungi. Seeds that are moist or immature when stored may become discolored due to heat (see also wrinkled and embryo-damaged seeds, discussed later).

Boron deficiency in peanuts results in seed discoloration (see also hollow heart, discussed later). Seed coat browning of broad bean is caused by calcium deficiency. Peanut seeds deficient in calcium often have darkened plumule, and the viability of seeds is directly related to their calcium concentration.

Reduced Seed Size

In general, plants grown in nutrient-deficient conditions produce seeds of reduced size. Soybean seed size is...
reduced when plants are grown in molybdenum-deficient conditions. Such seeds may produce plants that show deficiency symptoms when grown in soils with a marginal supply of this nutrient.

**Shrunken and Wrinkled Seeds**

Cold-damaged canola seeds become brown and shrunk-en. Wrinking of soybean seeds may occur due to moderate desiccation during maturation, resulting in lower field emergence than in seeds with sound coat. Self-heating of seeds during storage, particularly when the seed is moist or immature, may lead to wrinkling and discoloration. Severe potassium deficiency tends to result in wrinkled, misshapen soybean seeds.

**Hollow Heart**

Hollow heart, characterized by cavities or depression on the adaxial face of cotyledons (Fig 2), is a widely known seed disorder of pea. The disorder is caused by sudden drying of immature seeds at high temperatures. It is common in wrinkled pea seeds and peas having compound starch grains. Hollow heart symptoms are seen when seeds are soaked in water for 16–18 hours at 20–25°C, testae are separated, and the split cotyledons are stored for 24 hours at 20–25°C.

Seeds with hollow heart germinate normally under ideal conditions, but the disorder predisposes seedlings to attack by pathogenic fungi or results in poor emergence.

Hollow heart symptoms also occur in peanut seeds, in which case it is caused by boron deficiency. The symptoms include discoloration and rotting. The inner face of the cotyledon is depressed in the center, which region often turns brown, especially when peanuts are roasted.

**Marsh Spot**

Marsh spot of pea—characterized by discolored lesions in the center of the adaxial face of the cotyledon—is due to manganese deficiency (Fig. 3). The disorder is common in cultivars having simple and large starch granules in the cotyledons. Similar disorder due to manganese deficiency is found in seeds of broad bean, haricot bean, and runner bean. Marsh spot symptoms are also seen by the method described for hollow heart symptoms.

**Fig. 3** Marsh spot symptom showing discolored lesions in the center of the adaxial face of cotyledon of pea (right) and normal seed (left) (From Ref. 14). (View this art in color at www.dekker.com.)
Yellow Berry

Yellow berry is the term given to wheat grains that are light-yellow in color, opaque, soft, and starchy. They differ from the normally hard, flinty, translucent grains—clear and dark and reddish-amber in color—described in the U.S. state of Kansas.[8] Yellow berry is associated with nitrogen deficiency and warm temperatures during heading and seed maturation.[9] Such seeds germinate normally, but may result in poor market value. They are also high in starch content, but low in protein. The incidence of yellow berry differs among wheat genotypes.

Seeds with Holes and Pits

This disorder is caused by a wide range of insects feeding on seeds, causing holes and pits and sometimes leaving seeds completely empty (Fig. 4). Examples of such insects are species of *Bruchus*, *Heliothis*, *Lygus*, and *Sitophilus*. [3]

**INVISIBLE SEED DISORDERS**

Genetic Disorders

These disorders are transmitted through seeds, and include fruit pox, gold fleck, and corky stunt of tomato.[1] Fruit pox appears as incipient lesions on immature fruit, which later rupture and become necrotic before the fruit turns red. Gold fleck appears as small lesions on immature fruit, that turn golden-yellow on ripe fruit. Corky stunt is expressed as shortened internodes, proliferated axillary buds, malformed petioles, roughened lower petiole surfaces, and malformed and corked fruit. See the *Annotated List of Seed-borne Diseases* [10] for other examples of seed-transmitted disorders such as bud failure of almond and stem distortion of wheat.

Embryoless or Embryo-Damaged Seeds

Embryoless or embryo-damaged seeds are often found. The disorder is expressed in the form of either no germination or abnormal seedlings. Embryoless seeds are encountered in carrot, celery, coriander, dill, fennel, parsley, and parsnip seeds when insects such as lygus bugs (various species of *Lygus*) eat embryos but leave the seed coat and endosperm undamaged.[3] Due to some genetic effects, defective fertilization may take place in some crop plants, e.g., barley and wheat, resulting in embryoless seeds.[1]

Embryo damage may be caused by mechanical injuries, and results in abnormal seedlings. For example, mechanical damage of lima bean embryo during threshing results in balhead or snakehead seedlings that may lack a growing point, radicle, or cotyledon.[1,3] Similar damage occurs in peas and clover.[3] Heating of seeds due to metabolic activities during storage may lead to embryo damage and result in the production of abnormal seedlings.[3]

Seed Aging

Old seeds gradually decline in germination capacity and develop plants of reduced vigor and yield. Seeds stored under adverse conditions may also have reduced viability as a result of induced aging. Seeds stored at higher temperatures generally age early and show increased production of lipid peroxidase. This has been demonstrated in seeds of *Phaius tankervilliae*. [11] Blind plant problem (i.e., the lack of normal meristem) in tomato is mostly associated with old seeds.[12] Loss of viability with aging of niger seeds is associated with reduced radicle growth and abnormalities in hypocotyl development.[13] Aged seeds may also exhibit delays in germination, as in the case of meadow steppe grass seed.[14]

Chemical Injuries

Seeds treated with chemicals at excessive doses, stored at higher temperatures after treatment, and stored for a long period after treatment may undergo damage. Such seeds
either do not germinate or produce abnormal plants. For example, seed treated with organomercurial fungicides at excessive rates or high moisture either do not germinate or show hypertrophy of the coleoptile and poor root development. Some chemicals may cause phytotoxicity regardless of moisture content of treated seeds, time of sowing after treatment, and temperature, because they are toxic to certain kinds of seeds but beneficial to others. For example, fungicides like carbendazim + thiram and imidacloprid are found to be toxic to pea seeds.\(^{[15]}\)

### Nutrient Deficiencies

Seeds that look normal may be deficient in nutrients, especially micronutrients. Such seeds may produce abnormal seedlings when sown. Pea seeds deficient in boron develop seedlings with pale stunted shoots without plumule bud.\(^{[10]}\) Phaseolus bean seeds produced under molybdenum deficiency conditions give seedlings with scald symptoms.\(^{[10]}\)

### CONCLUSION

Noninfectious seed disorders can be genetic, physiogenic, or caused by injuries. Although the disorders are non-pathogenic, they may predispose the seeds to invasion by pathogenic and saprophytic organisms. The disorders are responsible for low germination, production of abnormal or diseased plants, and low market value. The types of disorders and their causes suggest that they can be managed by selecting proper genotypes of crop plants; adopting proper measures during harvesting, processing, and storage; and correcting nutrient deficiencies in soil and plants.

Non-Wood Plant Fibers: Applications in Pulp and Papermaking

Joseph E. Atchison
Atchison Consultants, Inc., Sarasota, Florida, U.S.A.

INTRODUCTION

It is well known that due to a plentiful supply and reasonable costs, the economics of pulp and paper production in North America, and in most other industrial countries, have favored wood as the fibrous raw material, in the past and up to the present time. However, many of the developing countries, as well as a few of the industrial countries, do not have adequate supplies of wood, but they do have large quantities of non-wood plant fibers available. Fortunately, we have found that by choosing the proper blend of non-wood plant fibers, almost all grades of paper and paperboard—ranging from tissue to linerboard, including newsprint—can be produced with as much as 100% fibrous content of these materials. Furthermore, every type of reconstituted panel board—ranging from insulating board to hardboard, including medium-density fiberboard—can likewise be produced, and is being produced, from non-wood plant fibers.

INCREASE IN CAPACITY IN PULPS PRODUCTION FROM NON-WOOD PLANT FIBERS: 1975–1998

Table 1 shows this rapid growth in production capacity for non-wood plant fiber pulps. It can also be seen that the average increase in non-wood plant fiber pulping capacity has been greater for many years (up until 1998) than the average increase in wood pulping capacity. For example, during the five-year period from 1988–1993, non-wood pulping capacity increased by 6.0% annually, whereas wood pulping capacity increased by only 2.0% annually.

Then during the 1993–1998 period, non-wood pulping capacity increased by 2.7% annually, in contrast to an increase of only 1.6% for wood pulping capacity.

Unfortunately, due to the financial crisis that began in 1997 in the Asian countries and some other developing countries that were major producers of non-wood plant fiber pulp, along with the worldwide recession in the pulp and paper industry (which continues today) and the fact that China has closed several thousand small non-wood plant fiber-based mills that did not have recovery systems, there has been no increase in non-wood plant fiber pulping capacity since 1998. Furthermore, no increased capacity is projected through 2003, as shown in the annual FAO Pulp and Paper Capacities Survey for 1998–2003.[5] However, it is the author’s opinion that as soon as the economic situation improves sufficiently in these countries, which are the major producers of non-wood plant fiber pulp, the previous trend upward will resume.

MINIMUM UTILIZATION OF NON-WOOD PLANT FIBERS IN THE UNITED STATES

In contrast to the worldwide use of non-wood plant fiber pulps, the capacity for producing these pulps for papermaking in the United States amounted to only 219,000 metric tons in 2001, whereas wood pulping capacity amounted to 64 million metric tons, as reported in the FAO Pulp and Paper Capacities Survey for 1998–2003.[5] No increase in either non-wood plant fiber pulping capacity or wood pulping capacity in the United States is projected through 2003, due to the continuing worldwide recession in the pulp and paper industry.

WORLDWIDE USE OF NON-WOOD PLANT FIBERS FOR PAPERMAKING PULP

and a great many of them result in a product having some desirable properties. However, when all of the economic factors and technical problems are taken into consideration, only a very few of the hundreds of thousands of non-wood plant fibers can qualify.

At the present time, on a worldwide basis, straw, sugar cane bagasse, and bamboo are the leading non-wood plant fibers being used. However, many others are being used in countries such as China and India that do not have adequate wood supplies, even for the mass-production grades. These include reeds and grasses of various types. In addition, many other high-cost non-wood plant fibers are being used all over the world, including in the United States. They produce pulps with special properties that are not found in any wood pulps. Such pulps, including flax fibers, cotton fibers, abaca, sisal, and cotton linters, are being used for the production of relatively small quantities of many high-priced specialty papers and paperboards.

**WORLDWIDE NON-WOOD PLANT FIBER PULPING CAPACITY BY COUNTRY (1993 AND 1998)**

Table 2, shows the total worldwide capacity for production of non-wood plant fiber pulp by the leading producers of such pulps, along with the percentage of their total papermaking pulp capacity devoted to using these raw materials in 1993 and 1998. These figures are based on data from the FAO Pulp and Paper Capacities Survey for 1993–1998, combined with individual reports received by Atchison Consultants in personal correspondence with some of the Pulp and Paper Associations of major non-wood plant fiber pulp-producing countries. As mentioned earlier in this chapter, there has been no increase in non-wood plant fiber pulping since 1998.

Some 42 countries are now producing some papermaking pulp from non-wood plant fibers, with the total capacity approaching 24 million metric tons (Table 2), or 11.0% of total worldwide papermaking pulp capacity. It can be seen that China is by far the leader, with 84% of its total papermaking pulp capacity devoted to pulping non-wood plant fibers. India is second, with over 64% of its capacity based on pulping non-wood plant fibers. Among the countries shown in Table 2, non-wood plant fiber represents 100% of the pulping raw materials in four of them, and nine of them depend upon these raw materials for more than 50% of their pulping capacity. Table 3 a summary of worldwide papermaking pulp capacities based on using specific non-wood plant fibers, as well as the total of wood-based pulping capacities and the overall percentages of pulping capacities based on using non-wood plant fibers.

**CONCLUSION**

There appears to be no doubt that non-wood plant fibers will play an increasing role in the world’s pulp and paper industry. Certainly, the necessary fiber resources either already exist or can be grown in the wood-poor countries, in order to sustain the pulp and paper requirements in those areas. It has been proved that by selecting the proper

mixture of these fibers and by the appropriate collecting, handling, storing, and pulping processes, any grade of paper, paperboard, or reconstituted panelboard can be produced from non-wood plant fibers. If circumstances require it, all grades can be produced without the addition of wood pulp. In fact, some grades are already being produced with 100% non-wood plant fiber, especially bagasse pulp. However, for most of the mass production grades it is expected that non-wood plant fiber pulps will be used in blends with at least a small proportion of wood pulp, even in the wood-poor countries.

In regard to the greater use of non-wood plant fiber pulps in North America, the time may be approaching when their greater use will become a reality. With 100 million metric tons of available straw; the potential of some 5 million tons of bagasse, with large concentrations of it available in Louisiana; 150 million metric tons of corn stover; and the exciting possibilities of kenaf, non-wood plant fiber certainly should be considered as supplementary raw materials to be blended with wood pulp.

Nucleic Acid Metabolism

Hiroshi Ashihara
Ochanomizu University, Tokyo, Japan

INTRODUCTION

Nucleic acid metabolism includes biosynthesis of nucleotides (phosphate esters of ribose or deoxyribose in which a purine or pyrimidine base is linked to C1’ of the sugar residue) for RNA and DNA, and degradation of these nucleic acids to simple molecules. The processes of DNA replication and repair, as well as the synthesis of various RNAs related to gene expression, are not included in this review. Compared with microorganisms and mammals,[1–3] only limited research has been carried out on the synthesis and degradation of nucleic acids in higher plants; some reviews of the subject have been published.[4–9]

DE NOVO BIOSYNTHESIS OF RIBONUCLEOTIDES

The pathways in the biosynthesis of nucleotides from their small molecule precursors are traditionally referred to as de novo pathways. In contrast, nucleotide synthetic pathways from preformed purine bases and nucleosides are called salvage pathways.

Pyrimidine Nucleotide Biosynthesis

The de novo pyrimidine biosynthetic pathway, also known as the orotate pathway, is defined as the formation of uridine 5’-monophosphate (UMP) from carbamoyl phosphate. The orotate pathway consists of six reactions, as shown in Fig. 1. The pyrimidine ring is assembled from carbamoyl phosphate and aspartate. The C-2 and N-3 atoms originate from carbamoyl phosphate; N-1, C-4, C-5, and C-6 originate from aspartate. In mammals and many other eukaryotes, the first three enzymes—carbamoyl-phosphate synthetase, aspartate transcarbamoylase, and dihydroorotase—are present as a multifunctional protein called CAD (after the initial letter of the three constituent enzymes). However, no such complex has been detected in plants, although most of the encoding genes for the individual enzymes have been cloned. Some of the genes contain chloroplast transit sequences. Thus, in higher plants, pyrimidine biosynthesis seems to be operative in chloroplasts.

Although there are two different types of carbamoyl phosphate synthetases that provide substrates for pyrimidine and arginine biosynthesis in most eukaryotes, including mammals, only one is present in higher plants. Therefore, the plant enzyme provides carbamoyl phosphate for both pathways. UMP, an end product of the orotate pathway, is a feedback inhibitor of plant carbamoyl phosphate synthetase, but this inhibition is overcome by ornithine, leading to the utilization of carbamoylphosphate for arginine biosynthesis. The second enzyme—aspartate transcarbamoylase—is also inhibited by high concentrations of UMP. This seems to be feedback control of pyrimidine biosynthesis.

The fourth enzyme—dihydroorotate dehydrogenase—is not well characterized. Subcellular localization studies with heterotrophically cultured tomato cells suggested that it is located in mitochondria. The fifth and sixth enzymes—orotate phosphoribosyltransferase and orotidine-5’-monophosphate decarboxylase—from plants, reside in a single polypeptide. Recently, a new term, UMP synthase, has been given to this multifunctional protein, which is also observed in animals. UMP produced by the orotate pathway is further phosphorylated by UMP kinase and nucleoside diphosphate kinase to UTP via UDP. CTP is formed from UTP by a one-step reaction catalyzed by CTP synthetase.

Purine Nucleotide Biosynthesis

The de novo purine biosynthetic pathway is defined as the pathway that is responsible for the synthesis of inosine 5’-monophosphate (IMP) from 5-phosphoribosylamine (PRA). PRA is formed from 5-phosphoribosyl-1-pyrophosphate (PRPP), a common phosphoribosyl donor for purine and pyrimidine nucleotide synthesis. The purine ring is assembled from several small molecules. The N-1 atom originates from aspartate; C-2 and C-8 are from activated derivatives of tetrahydrofolate; N-3 and N-9 come from the amide group of the side chain of glutamine; and C-4, C-5, and N-7 are from glycine. Fig. 2 shows the 10 steps of the IMP synthetic pathway from PRPP. Precise details of this pathway in plants are still obscure, but the
same biosynthetic pathway for IMP has been established in animals and microorganisms. In animals, enzymes of the de novo purine nucleotide biosynthetic pathway and those of hydrofolate metabolism are present as a multi-enzyme complex called a metabolon. However, such a complex has not been observed in higher plants. IMP is further converted to AMP and GMP. These two purine nucleoside 5'-monophosphates are phosphorylated to nucleoside diphosphates and finally to nucleoside triphosphates. Feedback control of the de novo purine biosynthetic pathway is performed in at least three steps: 5-phosphoribosylamine synthase activity is inhibited by IMP, AMP, and GMP. Activities of adenylosuccinate synthetase and IMP dehydrogenase are inhibited by AMP and GMP, respectively.

**BIOSYNTHESIS DEOXYRIBONUCLEOTIDES**

**Synthesis of Deoxyribonucleotides**

A single plant ribonucleotide reductase catalyses the reduction of the ribose moiety of the ribonucleotide diphosphates, and deoxyribonucleoside diphosphates (dNDP) are produced. With the exception of dUDP, dNDP are further phosphorylated and the resultants—dCTP, dATP, and dGTP—are utilized as direct precursors for DNA synthesis. For dTTP synthesis in plants and in microorganisms such as *E. coli*, dUDP formed by the ribonucleotide reductase is first converted to dUTP, and then hydrolyzed to dUMP. In contrast, dUMP is formed from dUDP in animals.
Fig. 2 De novo biosynthetic pathway of purine nucleotide biosynthesis in plants. Participating enzymes and genes are as follows: (1) amido phosphoribosyltransferase (2.4.2.14, pur1); (2) glycineamide ribonucleotide (GAR) synthetase (6.3.4.13, pur2); (3) GAR formyltransferase (2.1.2.2, pur3); (4) formyl glycine amidine ribonucleotide (FGAM) synthetase (6.3.5.3, pur4); (5) 5-imidazole ribonucleotide (AIR) synthetase (6.3.3.1, pur5); (6) AIR carboxylase (4.1.1.21, pur6); (7) 5-aminomimidazole-4-N-succinocarboxamide ribonucleotide (SAICAR) synthetase (6.3.2.6, pur7); (8) adenylosuccinate (SAMP) lyase (4.3.2.2, pur8); (9) 5-aminomimidazole-4-carboxamide ribonucleotide (AICAR) formyl transferase (2.1.2.3, pur9); (10) inosine 5'-monophosphate (IMP) cyclohydrolase (3.5.4.10, pur10); (11) SAMP synthetase (6.3.4.4, pur11); (12) SAMP lyase (4.3.2.2, pur12); (13) IMP dehydrogenase (1.2.1.205, pur13); (14) GMP synthetase (6.3.4.1, pur14). Gene names for plant purine metabolism have not yet standardized.
Synthesis of Thymidine Nucleotides

Thymidine nucleotide is synthesized from dUMP by the following reaction catalyzed by thymidylate synthase:

\[
\text{dUMP} + N^5, N^{10}\text{-methyltetrahydrofolate} \rightarrow \text{dTMP} + \text{dihydrofolate}
\]

In this reaction, \( N^5, N^{10}\text{-methyltetrahydrofolate} \) produced by dihydrofolate reductase acts both as donor of the methyl group and as reducing agent. A bifunctional protein that consists of thymidylate synthase and dihydrofolate reductase has been detected in plants.

SALVAGE PATHWAYS

Free nucleosides (nucleobases with sugar attached in a glycosidic linkage) and nucleobases (purines and pyrimidines that are incorporated into nucleic acids and nucleotides) are produced as degradation products of nucleic acids and nucleotides. Pyrimidine and purine nucleotides can be resynthesized using these preformed pyrimidine and purine skeletons by various salvage reactions.

Pyrimidine Salvage

Uracil, one of the pyrimidine bases, is salvaged by uracil phosphoribosyltransferase, but another base—cytosine—is not salvaged by any enzymes. Pyrimidine nucleosides, uridine, cytidine, deoxycytidine, and thymidine are salvaged to their respective nucleotides, UMP, CMP, dCMP, and dTMP. Uridine and cytidine are phosphorylated by a single enzyme, uridine/cytidine kinase, which is present in all plants investigated to date. Deoxycytidine kinase and thymidine kinase may be present in plants, but details of their activity have yet to be reported. Nonspecific nucleoside phosphotransferase activity also participates in the salvage of pyrimidine nucleosides as well as purine nucleosides. Thymidine kinase activity measured in crude plant extracts seems to be due to the activity of nucleoside phosphotransferase and phosphatases.

Purine Salvage

Three purine bases—adenine, guanine, and hypoxanthine—are salvaged to AMP, GMP, and IMP, respectively. Two distinct enzymes—adenine phosphoribosyltransferase and hypoxanthine/guanine phosphoribosyltransferase—participate in these salvage reactions. Purine bases may also be salvaged to nucleotides via nucleosides. Adenosine phosphorylase and inosine-guanosine phosphorylase convert adenine, hypoxanthine, and guanine to respective ribonucleosides using ribose-1-phosphate, but activities of these enzymes are very low in higher plants.

Purine nucleosides, adenosine, guanosine, and inosine are salvaged by kinases and/or nucleoside phosphotransferase. Adenosine kinase is distributed ubiquitously and its activity is high, but inosine-guanosine kinase has only been found in limited plant species. In some plants, inosine and guanosine are mainly salvaged by the nonspecific nucleoside phosphotransferase.

NUCLIC ACID SYNTHESIS

Four ribonucleoside triphosphates—UTP, CTP, ATP, and GTP—are used for the precursor of the synthesis of various RNAs, whereas dTTP, dCTP, dATP, and dGTP are used as the building blocks of DNA. Pool sizes of individual ribonucleotides vary greatly because they are not only the building blocks for RNA but also have other important functions, such as energy transfer. Thus, the ATP pool is always higher than other nucleotide pools, and the CTP pool is very small. The size of deoxyribonucleotide pools is extremely small compared with ribonucleotides; as a consequence, no direct measurements of these nucleotides have yet been carried out with plants.

DEGRADATION OF NUCLEIC ACIDS

DNA and RNA are hydrolyzed by deoxyribonucleases (DNases) and ribonucleases (RNases), respectively. Oligonucleotides formed by these enzymes further hydrolyzed to nucleoside monophosphates by phosphodiesterases with 2', 3', and 5'-nucleoside monophosphates being produced. Some of these nucleotides are catabolized by nucleotidases and/or phosphatases and nucleosides accumulate. Furthermore, in plants, nucleosides are hydrolyzed exclusively by nucleosidases to nucleobases. Significant amounts of free nucleosides and nucleobases are produced, because the degradation products of nucleic acids seem to be salvaged within the same cells or transported to other organs, e.g., from senescent leaves to young shoots. The remainder will be completely degraded to CO\(_2\) and NH\(_3\).

DEGRADATION OF NUCLEOTIDES

Pyrimidine Catabolism

In plants, pyrimidine nucleotides are degraded to nucleoside and nucleobases. Pyrimidine bases, uracil, and thymine are catabolized by a reductive pathway. There is
A) Pyrimidine catabolism

Fig. 3 Catabolic pathways of pyrimidine and purine nucleotides in plants. Pyrimidine and purine catabolism are shown in A and B separately. Participating enzymes are as follows: A: (1) 5'-nucleotidase (3.1.3.5); (2) cytidine deaminase (3.5.4.5); (3) uridine nucleosidase (3.2.2.3); (4) dihydrouracil dehydrogenase (1.3.1.1); (5) dihydropyriminase (3.5.2.2); (6) β-ureidopropionase (3.5.1.6). B: (1) AMP deaminase (3.5.4.6); (2) IMP dehydrogenase (1.1.1.205); (3) 5'-nucleotidase (3.1.3.5); (4) inosine-guanosine nucleosidase (3.2.2.2); (5) guanosine deaminase (3.5.4.3); (6) guanine deaminase (3.5.4.3); (7) xanthine dehydrogenase (1.1.1.204); (8) uricase (1.7.3.3); (9) allantoinase (3.5.2.5); (10) allantoicase (3.5.3.4); (11) ureidoglycolate lyase (4.3.2.3); (12) urease (3.5.1.5); (13) allantoin deaminase (3.5.3.9); (14) ureidoglycine amidohydrolase (no EC number given); (15) ureidoglycolate hydrolase (3.5.3.19). Gene names for most enzymes of nucleotide catabolism in plants have not yet been given.

B) Purine catabolism
no catabolic pathway of cytosine in plants; thus, catabolism of CMP must be performed after conversion of cytidine to uridine. Plants have cytidine deaminase, but not cytosine deaminase, so conversion at nucleoside level is essential. Uracil and thymine are catabolized by the same three sequential reactions. The end products of this catabolic pathway are either β-alanine or β-aminoisobutyrate (Fig. 3A). In both cases, CO₂ and NH₃ are produced as by-products. Because β-alanine is a precursor of the pantothenate moiety of coenzyme A, uracil catabolism seems to be important as the biosynthetic pathway of β-alanine in plants.

**Purine Catabolism**

Plants possess the complete oxidative purine catabolic pathway to CO₂ and NH₃ via uric acid and allantoin. A key starting compound of purine catabolism is xanthine; thus, all purine nucleotides must be converted to xanthine before their purine ring cleavage is initiated. Deamination, dephosphorylation, and glycosidic bond cleavage are included in this process. In contrast to animals, in most plants no adenosine deaminase is found, and AMP deaminase and guanosine deaminase are the predominant deamination enzymes for adenine and guanine nucleotides, respectively. Guanine deaminase is also detected in plants, but its activity is low. GMP reductase, which catalyses the conversion of GMP to IMP, is not present in plants. There are many enzymes for dephosphorylation reaction. Various phosphatases, 3'-nucleotidase, and 5'-nucleotidase appear to produce purine nucleosides. Adenosine nucleosidase and inosine-guanosine nucleosidase seem to participate in glycosidic bond cleavage (Fig. 3B).

Xanthine is converted to uric acid by xanthine dehydrogenase. Uricase catalyzes the formation of allantoin, and allantoic acid is produced by an allantoinase-catalyzed reaction. Some plant organs, such as roots of the tropical legumes and maple trees, accumulate allantoin and/or allantoic acid, which play an important role in the storage and translocation of nitrogen. Different metabolic fates of allantoic acid are proposed in plants.

In the classic allantoicase pathway, allantoin is degraded to CO₂, NH₃, and glyoxylate via urea and ureidoglycolate. Recently an alternative route, an allantoic acid amidohydrolase pathway, has been proposed in which allantoic acid is initially converted to ureidoglycine, CO₂, and NH₃. The NH₃ is released directly and urea formation is not involved.

**REFERENCES**

INTRODUCTION

Functional foods are foods that provide health benefits beyond basic nutrition. Functional foods cater to both ill and healthy, and target prevention and treatment of illness, as well as maintenance of one’s well-being. Products in the market range from complete portfolios of prepared meals that battle cardiovascular and type II diabetes, to fortified drinks and cereals that provide supplemental minerals, vitamins, and fiber.

Nutraceuticals are isolates that provide concentrated nutrients in the form of pills, tablets, liquids, or powders for direct consumption or for use as ingredients in functional foods. Nutraceuticals include micro- and macronutrient isolates, herbs and botanicals, and isolated reagents (e.g., hormones).

DRIVERS OF INNOVATION

Traditional remedies utilizing plants and animals to cure disease and improve health and well-being have existed for centuries and have been passed down through generations. In the mid-1980s, clinical studies began to formalize the relationship between nutrition and healthfulness, attracting significant attention from both media and consumers. First among these studies was the 1984 National Cancer Institute certification that high-fiber cereals foster cardiovascular health. Since that time, the body of literature connecting nutrition to specific health benefits and disease treatment has increased substantially, and other foods (e.g., calcium, omega-3 fatty acids, whole oats, and soy protein) have gained similar certification by the U.S. Food and Drug Administration (FDA).

Scientific discovery in the development of new products capable of delivering specific health benefits has also advanced rapidly. Cholesterol reduction, cardiovascular disease, and osteoporosis have become the most frequent targets for functional foods and nutraceuticals, followed by child development, moodiness, low energy, high blood pressure, diabetes, gastrointestinal (GI) disorders, menopause, and lactose intolerance.

Consumer interest has bolstered new product development of nutraceuticals and functional foods. An aging and wealthier population in Japan, the European Union (E.U.), and the United States has become increasingly interested in the prevention of disease and health maintenance, representing a receptive audience to health claims. Similarly, escalating health care costs and increasing interest in self-medication have shifted attention to health maintenance and disease prevention instead of treatment. Table 1 provides some examples of nutraceuticals and functional foods introduced in recent years.

MARKET SIZE AND GROWTH

In 2001, the global market for functional foods was estimated at over $47.6 billion. Well developed food markets accounted for the majority of the global consumption of functional foods. The U.S. functional foods market alone was valued at $18.25 billion, representing 3.7% of the $495 billion spent for food at home by U.S. consumers. The European Union and Japan followed with $15.4 billion and $11.8 billion in functional food sales, respectively. Consumer spending on functional foods is expected to grow at a fast rate although not evenly across all food categories. In recent years, functional beverages have experienced the fastest growth (Table 2).

Not all functional foods have been successful in the marketplace. Some products have seen diminished consumer demand due to unexpected negative side effects (e.g., the fat substitute Olestra). Others have been quietly removed from supermarket shelves due to lack of sufficient consumer demand (e.g., McNeil’s Benecol in the United States; Kellogg’s Ensemble; and Cambell Soup Company’s Intelligent Cuisine).

The global market for nutraceuticals reached $50.6 billion in 2001. Vitamin/mineral supplements accounted for 40% ($20.6 billion) of those sales, followed by herbs and botanicals ($19.6 billion) and sports/specialty supplements ($10.4 billion). Vitamins are especially important in the U.S. market, whereas herbs are relatively more important in the European and Asian markets, which have a long tradition of herbal use and remedies.
PRODUCT INNOVATION AND INDUSTRIAL DEVELOPMENT

For continuing growth in the nutraceuticals and functional foods markets, sustained technological innovation will continue to be critical. The scope of innovation will likely range from product functionality, to taste characterization and manufacturing. This will require the pooling of knowledge, skills, and infrastructure from industries that have not worked closely together in the past. For example, nutraceutical startups and biotechnology firms may contribute discoveries in new products and attributes. Food companies may provide product formulation, manufacturing, and distribution capabilities. Pharmaceutical companies may contribute discovery and knowledge in amplification of efficacy, as well as experience in the validation of safety (e.g., clinical trials).

Major food companies making significant investments in functional foods are already pursuing integration of skills and assets. Many of these companies have moved to acquire diverse skills through acquisitions or strategic alliances. For instance, PepsiCo recently acquired Gatorade and Sobe functional beverage brands; Heinz acquired a share in Hain Foods, a processor of soy and natural foods; and Quaker and Novartis entered into a joint venture to form Altus Food Company, which is dedicated to the development of functional foods.

To be successful, this emergent industry will have to learn how to develop products that deliver functionality in ways that appeal to changing consumer tastes and lifestyles. It will also have to learn how to protect and recoup its investments (e.g., R & D) through patents, brands and trademarks, and other marketing strategies. Finally, this new industry will have to learn how to position functionality claims within an uncertain and fragmented regulatory environment.

INSTITUTIONAL INNOVATION

It will be up to governments to establish relevant institutional environments that create appropriate incentives
for research and development in nutraceuticals and functional foods while they protect public health and consumer interests. Meaningful institutional innovation will therefore be necessary in coming years. Current regulation lacks clear standards on health claims (efficacy), product quality, and safety that can impede market development. For instance, the slow market development experienced in herbs/botanicals (a flat 1.2% rate of growth in 2000) has been attributed to the high incidence of low-quality (and occasionally unsafe) products introduced during the boom market of the late 1990s.\[7\] Herbs contaminated with heavy metals, heart problems attributed to Ephedra, and safety concerns with sports supplements (e.g., Androstenedione, or Andro) attracted significant negative public attention and reduced consumer interest.

Development of a proper regulatory framework has been complicated by the dualistic food and drug nature of nutraceuticals and functional foods. Complexities are likely to increase in the future as active ingredients become more powerful, requiring some foods to be regulated as pharmaceuticals. For instance, pharmaceutical foods (such as edible vaccines) are already under development. These bioengineered foods are being developed to express specific pharmaceutical compounds, providing a convenient drug manufacturing and delivery mechanism. Accordingly, an institutional environment capable of efficiently regulating both foods as drugs and drugs as foods will be necessary.\[8\]

Currently, there are few regulatory standards, and those that exist fail to transcend national borders. The U.S. system is characterized by a dichotomy of regulatory stringency, wherein some products can be commercialized with minimal regulatory oversight, while others are strictly regulated. Less-regulated products are allowed by the Dietary Supplement Health and Education Act (DSHEA), which shifted the burden of proving an ingredient unsafe from the manufacturer to the FDA. Under DSHEA guidelines, a dietary supplement may include a vitamin, mineral, herb/botanical, amino acid, metabolite, or an extract. Laws allow nutritional support statements such as those relating to classical nutrient-deficiency diseases, structure/function, or well-being, provided they include the following disclaimers: “This statement has not been evaluated by the Food and Drug Administration’’ or “This product is not intended to diagnose, treat, cure, or prevent any disease.’’

In order to make health claims linking a food or dietary supplement to a disease or health-related condition, premarket approval by the FDA is required. The FDA approval process is dependent on scientific consensus identifying a specific functional component responsible for physiological action. The approved health claim must include the appropriate dietary context (e.g., low in saturated fat and cholesterol), which can then be used with any similar product, not just those produced by the petitioner.

The main obstacle for the European system is the lack of standard protocols across national borders. For example, France and Germany differ from the United States and many other European countries in that French and German herbal drugs are distributed via pharmacies, allowing for doctor mediation and reimbursement by health insurance.

In contrast to the U.S. and European models, the Japanese nutraceuticals and functional foods markets are highly regulated and supported. Since 1991, the Japanese government has actively promoted the development of functional foods through the Foods for Specialized Health Use (FOSHU) system. Foods in this product category can secure regulatory approval to make specific health claims, and are educationally supported by the program. FOSHU is an umbrella label for all functional foods, and ensures safety and efficacy; however, FOSHU is not mandatory and the manufacturers of some functional products opt to circumvent it, suggesting that subpar products may still be commercialized. This Japanese system has been popularly proposed as a potential template for the development of international standards. The development of such international standards, however, has progressed slowly (until now).

**CONCLUSION**

It is clear that both scientific discoveries and consumer interest are creating opportunities for an expanding menu of foods and supplements that claim health benefits beyond nutrition. In globalized markets where products are traded across national borders at an increasing pace, a proper regulatory framework for how such claims are brought forward will be increasingly important. Hence, consumers, scientists, entrepreneurs, and regulators will all shape the rate and direction of product innovation in the nascent markets of nutraceuticals and functional foods for many years to come.

Oomycete-Plant Interactions: Current Issues in

Mark Gijzen
Agriculture and Agri-Food Canada, London, Ontario, Canada

INTRODUCTION

The oomycetes (water molds) are related to the brown algae and diatoms. Oomycetes resemble fungi morphologically, but are now classified separately based on their natural phylogeny. Oomycetes have coenocytic hyphae with cell walls consisting mainly of cellulose and glucans. They are diploid throughout most of their life cycle and reproduce sexually by formation of thick-walled oospores, or asexually by zoospores or sporangia. Heterothallic species require different mating types to produce oospores, whereas homothallic species are self-fertile. Oomycetes include hundreds of plant pathogenic species distributed across several genera, including *Albugo*, *Aphanomyces*, *Bremia*, *Peronospora*, *Phytophthora*, *Plasmopara*, and *Pythium*. Plant pathogenic oomycetes may be necrotrophic, biotrophic, or hemibiotrophic species. Many studies on oomycete–plant interactions focus on the *Phytophthora* species, an especially destructive and widespread genus. Genetic and molecular-level research on oomycetes is gaining momentum; new insights into processes that control virulence and pathogenicity are emerging.

OMYCETES AS PLANT PATHOGENS

Oomycetes display a range of pathogenic strategies in colonizing host tissues. Necrotrophs such as *Pythium* are considered facultative parasites that kill host cells in advance of infection. *Pythium* also include many saprophytic species that simply live off dead tissue and are not true pathogens. Obligate biotrophs such as *Bremia* and *Peronospora* require living host cells and cannot be grown in culture. Many *Phytophthora* spp. are intermediate types (hemibiotrophs) that first establish in living cells as biotrophs but more closely resemble necrotrophs at later stages of infection. An evolutionary sequence has been proposed whereby saprophytes give rise to necrotrophic organisms, which in turn may further evolve into hemibiotrophs, and ultimately, into obligate biotrophs. The oomycetes present compelling evidence in support of this theory because their spectrum of pathogenic strategies is generally concordant with their phylogeny. It is clear that these different colonization strategies result in different mechanisms of infection, but there may remain commonalities among different pathogen types. For example, the subversion of host plant metabolism and the suppression of many chemical and structural defense responses would benefit any pathogen, whether biotroph or necrotroph. In contrast, pathogen-induced host cell death by secretion of toxins or by manipulation of endogenous cell death programs may be predicted to benefit the pathogen in necrotrophic but not biotrophic interactions.

The oomycetes are considered versatile and adaptable plant pathogens for other reasons as well. These organisms attack a wide range of herbaceous and woody plants in many different environments. Host specificity may be broad or restricted to a single plant species. Most *Pythium* species have wide host ranges, whereas the biotrophic species *Bremia* and *Peronospora* are highly specialized with one or few host plants. *Phytophthora* species may have broad or narrow host ranges.

Contemporary studies on plant pathogenic oomycetes address many different species, but a few organisms are attracting a critical mass of researchers and resources. Emerging as model systems for molecular genetic and genomic studies on oomycetes are *Phytophthora infestans* and *Phytophthora sojae*. *P. infestans* is a heterothallic species that causes late blight of potato and tomato. This is predominately a foliar pathogen, but is also able to infect tubers. Outbreaks of *P. infestans* are spread via airborne sporangia. *P. sojae* is a homothallic oomycete that causes root and stem rot of soybean, as shown in Fig. 1. This soilborne pathogen produces motile zoospores that spread in water and are attracted to soybean roots. Oospores are also abundantly produced in infected tissues, and these propagules are long-lived in soil and may be spread by animals or machinery.

Genetic studies on oomycetes have benefited from advances in molecular biology. It is now possible to distinguish hybrid progeny from self-fertile individuals based on DNA markers, and to create *F*₂ progeny sets. This has enabled researchers to perform classical genetic analyses of oomycetes, and has confirmed that many oomycete–plant interactions are governed by complementary avirulence (*Avr*) and resistance (*R*) genes. Genetic analyses of *Bremia lactucae*, *P. infestans*, *P. sojae*, and *Peronospora parasitica* indicate that, although exceptions have been noted, *Avr* genes segregate as single dominant loci and some *Avr* genes occur in clusters or
as tightly linked loci. Various Avr loci comprise targets for positional cloning projects in these species.\[4\]

**OOMYCETE ELICITORS AND TOXINS**

Interactions between pathogens and their hosts involve multiple signaling cues that ultimately determine whether the infection is successful. Elicitors and toxins have overlapping activities and each may trigger a similar set of plant defense responses, such as necrosis, phytoalexin accumulation, and cell death. Functionally, elicitors are generally regarded as molecules that aid the host by initiating defense reactions that contain the pathogen, whereas toxins are considered virulence factors produced by the pathogen to disable the host.\[5\] Among the first elicitors purified and characterized from a plant pathogen was a β-glucan elicitor from *P. sojae*. This is released from the cell walls of *P. sojae* by glucanase enzymes secreted by soybean cells. As a counter-defense, *P. sojae* produces inhibitors of the soybean-secreted glucanase enzymes, to slow cell wall digestion and elicitor release. This example provides evidence for the “escalating arms race” hypothesis of plant-pathogen interactions.

Many oomycetes, including *Phytophthora* and *Pythium* species, secrete small cysteine-rich proteins called elicitins. These 10 kD proteins elicit the hypersensitive response in certain plants, most notably in tobacco and other *Nicotiana* species. Larger proteins containing elicitin domains fused to other sequences may also be active. Most *Phytophthora parasitica* strains that are pathogenic on tobacco do not secrete elicitin because these proteins may act as host-specific avirulence determinants, limiting *Phytophthora* infections on tobacco plants. Elicitins have been shown to possess sterol- and lipid-binding activity, and their elicitor activity is also dependent on sterol binding. It is possible that elicitins function as carriers for the acquisition or transport of sterols or lipids. The elicitin protein family is large and diverse, and it is likely that this diversity is also reflected in their functional roles.

Several other *Phytophthora* proteins with elicitor or toxin activity have been described\[3\] as follows:

- A 42 kD transglutaminase protein secreted by *Phytophthora* species induces phytoalexin accumulation and other defense responses in parsley. The elicitor activity of the protein is dependent on the same residues that are necessary for catalytic activity, and this peptide signature has been proposed to constitute a pathogen-associated molecular pattern for *Phytophthora*.
- A 34 kD glycoprotein first purified from *Phytophthora parasitica* induces necrosis and defense gene expression in tobacco. This protein has cellulose-binding activity and plays a role in the adhesion of *Phytophthora* to plant cells.
- A 25 kD protein purified from *Pythium* and *Phytophthora* species is remarkable in its ability to cause plant cell death in a wide range of dicotyledonous plants. It is similar to proteins discovered in unrelated organisms that are also plant pathogens or saprophytes, such as fungi and bacteria.
- A 5.6 kD phytotoxic protein from *Phytophthora cactorum* has been shown to cause necrosis on strawberry and tomato plants.

These examples illustrate that many different factors may contribute to disease symptoms and cell death in oomycete-plant interactions. The proteins may be important factors that enable *Phytophthora* to invade host plants, or alternatively, provide cues for host plant surveillance systems aimed at limiting pathogen spread.

**PLANT RESISTANCE TO OOMYCETE PATHOGENS**

Because it is a host to several different oomycetes, including *Per. parasitica* and *Phytophthora brassicae*, *Arabidopsis thaliana* provides a powerful model for genetic dissection of mechanisms of plant resistance to oomycete pathogens. Resistance to the downy mildew pathogen has been most intensively studied and several different *RPP* genes, conditioning resistance to *Per. parasitica*, have been isolated from *A. thaliana*.\[6\] Other plant genes resistant to oomycete pathogens that have been isolated include the lettuce *Dm3* gene, controlling...
resistance to *Bremia lactucae*, and the potato *R1* gene, for resistance to *P. infestans*. There are common features among these resistance genes, as they all encode proteins that are predicted to occur within the cell, with nucleotide-binding site (NBS) and leucine-rich repeat (LRR) motifs.

The hypersensitive response (HR)—a programmed cell death of plants—has been proposed as a general mechanism conditioning plant resistance to oomycete pathogens. This occurs in the early stages of infection during initial penetration of host cells. Zoospores or sporangia germinate on the surface of host tissues and may form appressoria like structures at penetration points, as shown in Fig. 2. Studies on *P. sojae* and *P. infestans* indicate that when host cells at the initial infection site undergo HR quickly, much more effective containment of pathogen spread results. A lack of host recognition—as evidenced by no HR or a slow HR upon infection—permits the pathogen to grow further and colonize adjacent cells, resulting in disease. Later during the infection process, host cell death occurs extensively but does not limit pathogen spread, especially in the case of hemibiotrophic pathogens such as *P. infestans* and *P. sojae*. At this stage host cell death may even accelerate disease.

**CONCLUSION**

Oomycetes are destructive plant pathogens that harm crops, ornamental plants, and natural environments. Many have the potential to spread rapidly and cause severe epidemics when presented with suitable conditions. Nineteenth century disease outbreaks caused by oomycetes were important in the development of plant pathology as a scientific discipline and changed the practice of agriculture. Oomycetes continue to cause epidemics and serious problems to this day, most recently exemplified by the emergence of sudden oak death (*Phytophthora ramorum*) in central California. Oomycetes are successful pathogens that present many challenges as experimental organisms in the laboratory, but concerted efforts and advances in technology are leading to a better understanding of their biology. This holds the promise that more effective control measures will be developed to limit the damage caused by oomycetes throughout the world.

Organic Agriculture as a Form of Sustainable Agriculture

John P. Reganold
Washington State University, Pullman, Washington, U.S.A.

INTRODUCTION

During the past decade, organic farming became one of the fastest growing segments of agriculture all over the world.\[1,2\] Organic agriculture, sometimes called biological or ecological agriculture, combines traditional conservation-minded farming methods with modern farming technologies. It virtually excludes such conventional inputs as synthetic fertilizers, pesticides, and pharmaceuticals. Instead, it uses naturally derived chemicals or products as defined by organic certification programs, and it emphasizes building up the soil with compost additions and animal and green manures, controlling pests naturally, rotating crops, and diversifying crops and livestock.\[3\]

The goal of organic agriculture is to create sustainable agricultural systems. This article discusses organic agriculture and sustainability, organic agricultural practices, the history and extent of organic agriculture, and organic certification.

ORGANIC AGRICULTURE AND SUSTAINABILITY

Organic agriculture addresses many serious problems afflicting world food production: high energy costs, groundwater contamination, soil erosion, loss of productivity, depletion of fossil resources, low farm incomes, and risks to human health and wildlife habitats. However, just because a farm is organic does not mean that it is sustainable. For any farm to be sustainable, whether it be organic or conventional, it must produce adequate high-quality yields, be profitable, protect the environment, conserve resources, and be socially responsible over the long term.\[4\] So, if an organic farm produces high yields of nutritious food and is environmentally friendly and energy efficient, but is not profitable—then it is not sustainable. Likewise, a conventional farm that meets all the sustainability criteria but pollutes a nearby river with sediment because of soil erosion is not sustainable.

Organic farming systems have been shown to be energy-efficient, environmentally sound, productive, stable, and tending toward long-term sustainability.\[5,6\] Organic farming systems do not represent a return to the past. They use modern equipment, certified seed, soil and water conservation practices, improved crop varieties, and the latest innovations in feeding and handling livestock. Organic farming systems range from strict closed-cycle systems that go beyond organic certification guidelines by limiting external inputs as much as possible, to more standard systems that simply follow organic certification guidelines. They rely largely on available resources found on or near the farm. The protection of soil and the environment is fundamental to organic farming.

Yields from organic farms are usually somewhat lower than, but sometimes equal to, those from conventional farms, but they are frequently offset by price premiums that lead to equal or greater net returns. Research comparing the agronomic, economic, and ecological performance of organic and conventional farming systems confirms this. In fact, studies\[5,7,8\] generally have found that organic systems have equal or somewhat lower yields, but less variability in production from year to year; are equally, if not more profitable; cause less erosion and pollution; have better soil quality; are more energy efficient; and rely less on government subsidies than their conventional counterparts. In other words, the organic systems are more sustainable.

ORGANIC AGRICULTURAL PRACTICES

Organic farming systems rely on ecologically based practices. A central component of organic farming systems is the rotation of crops—a planned succession of various crops grown on one field. When crops are rotated, the yields are usually about 10% higher than when they grow in monoculture (growing the same crop on the same field year after year). In most cases, monocultures can be perpetuated only by adding large amounts of fertilizer and pesticide. Rotating crops provides better weed and insect control, less disease buildup, more efficient nutrient cycling, and other benefits. Alternating two crops, such as corn and soybeans, is considered a simple rotation. More complex rotations require three or more crops and often a four- to seven-year (or more) cycle to complete. In growing a more diversified group of crops in rotation, a farmer is less affected by price fluctuations of one or two crops. This may result in more year-to-year financial stability. There are disadvantages, too, however. They include the
need for more equipment to grow a number of different
crops, the reduction of acreage planted with government-
supported crops, and the need for more time and infor-
mation to manage more crops.

Organic agriculture not only has a diverse assortment
of crops in rotation, but also maintains diversity from
mixing species and varieties of crops and from system-
atically integrating crops, trees, and livestock. When most
of North Dakota experienced a severe drought during the
1988 growing season, for example, many monocropping
wheat farmers had no grain to harvest. Organic farmers
with more diversified systems, however, had sales of their
livestock to fall back on or were able to harvest their late-
seeded crops or drought-tolerant varieties.

Maintaining healthy soils by regularly adding crop
residues, manures, and other organic materials to the soil is
another central feature of organic farming. Organic matter
improves soil structure, increases its water storage capac-
ity, enhances fertility, and promotes the tilth, or physical
condition, of the soil. The better the tilth, the more easily
the soil can be tilled or direct-drilled with seed, and the
easier it is for seedlings to emerge and for roots to extend
downward. Water readily infiltrates soils with good tilth,
thereby minimizing surface runoff and soil erosion. Organic materials also feed earthworms and soil microbes.

The main sources of plant nutrients in organic farming
systems are green manures, composted animal manures
and plant materials, and plant residues. A green manure
crop is a grass or legume that is plowed into the soil or
surface-mulched at the end of a growing season to
enhance soil productivity and tilth. Green manures help to
control weeds, insect pests, and soil erosion, while also
providing forage for livestock and cover for wildlife.

Organic farmers use disease-resistant crop varieties and
biological controls (such as natural predators or parasites
that keep pest populations below injurious levels). They
also select tillage methods, planting times, crop rotations,
and plant-residue management practices to optimize the
environment for beneficial insects that control pest spe-
cies, or to deprive pests of a habitat. Organically certified
pesticides, usually used as a last resort to control insects,
diseases, and weeds, are applied when pests are most
vulnerable or when any beneficial species and natural
predators are least likely to be harmed.

**HISTORY AND EXTENT OF ORGANIC AGRICULTURE**

European organic agriculture emerged in 1924 when
Rudolf Steiner held his course on biodynamic agriculture.
In the 1930s and 1940s, organic agriculture was developed
in Britain by Lady Eve Balfour and Sir Albert Howard, in
Switzerland by Hans Mueller, in the United States by J. I.
Rodale, and in Japan by Masanobu Fukuoka. Since the
beginning of the 1990s, development of organic agricul-
ture in Europe has been supported by government subsi-
dies. In many other countries of the world, organic
agriculture was established because of the growing de-
mand for organic products in Europe, the United States,
and Japan. Today, organic farming is gaining increasing
acceptance by the public at large.

Organic agriculture is practiced in almost all countries
of the world, and its share of agricultural land and farms
is growing everywhere. In 2001 more than 17 million
hectares were managed organically worldwide. The
major part of this area is located in Australia (7.7 million
hectares), Argentina (2.8 million hectares) and Italy (more
than 1 million hectares). Oceania holds 45% of the world’s
organic land, followed by Europe (25%), and Latin
America (22%). In North America more than 1.3 million
hectares are managed organically. In most Asian and Af-
rican countries the area under organic management is still
low. Tables 1 and 2 show the top 20 countries in the world
with the most organically managed land and with the grea-
test proportion of total agricultural land in the country in
organic production.

**ORGANIC CERTIFICATION**

Growers are turning to certified organic farming systems
as a potential way to lower input costs, decrease reliance
on nonrenewable resources, capture high-value markets
and premium prices, and boost farm income. Organic
certification provides verification that products are
indeed produced according to certain standards. For
consumers who want to buy organic foods, the organic
certification standards ensure that they can be confident
in knowing what they are buying. For farmers, these
standards create clear guidelines on how to take
advantage of the exploding demand for organic products.
For the organic products industry, these standards
provide an important marketing tool to help boost trade
in organic products.

“Certified organic” means that agricultural products
have been grown and processed according to the specific
standards of various national, state, or private certification
organizations. Certifying agents review applications from
farmers and processors for certification eligibility, and
qualified inspectors conduct annual onsite inspections of
their operations. Inspectors talk with producers and ob-
serve their production or processing practices to determine
if they are in compliance with organic standards.

Organic certification standards detail the methods,
practices, and substances that can be used in producing
and handling organic crops and livestock, as well as
processed products. For example, in December 2000 the

(From Ref. 9.)
U.S. Department of Agriculture announced final national standards that food labeled “organic” must meet, whether it is grown in the United States or imported from other countries. These standards specifically prohibit the use of genetic engineering methods, ionizing radiation, and sewage sludge for fertilization. They went into labeling effect in October 2002.

On a broader scale, the International Federation of Organic Agriculture Movements (IFOAM) established the IFOAM Accreditation Programme to provide international equivalency of certification bodies worldwide. IFOAM accreditation is based on the international IFOAM standards, which are developed continually by the IFOAM membership, a democratic structure open to all who work in the field of organic agriculture and production. In 2000 the first products with the “IFOAM-accredited” logo came on the market. By early 2002, 17 organizations had been IFOAM-accredited.

Osmotic Adjustment and Osmoregulation

Neil C. Turner
CSIRO Plant Industry, Wembley, Australia

INTRODUCTION

Water deficits and lowering the osmotic potential of the external solution have long been known to induce a decrease in the osmotic potential or an increase in the osmotic pressure of higher plant cells.[1–3] This occurs as water is extracted from the cell from the passive concentration of the solutes present in the fully turgid cells. Under these circumstances, the osmotic pressure (\(P\)) of a cell is inversely related to the osmotic volume (\(V\)):

\[ P = \frac{\Pi_{100}V_{100}}{V} \] (1)

where \(\Pi_{100}\) and \(V_{100}\) are the osmotic pressure and osmotic volume, respectively, at full turgor.

RECENT DEVELOPMENTS

More recently it was recognised that higher plants can accumulate solutes in response to a water deficit, a process termed osmotic adjustment or osmoregulation. Although previous studies had shown that root turgor was maintained as soil-water deficits increased and seasonal changes in osmotic pressure mirrored seasonal changes in water potential,[3] the possibility of solute redistribution, uptake of solutes from the soil, and changes in elasticity could not be eliminated in these previous studies.[3] The first unequivocal increase in osmotic pressure in response to a soil-water deficit was reported by Jones and Turner,[4,5] who showed that osmotic adjustment in sorghum and sunflower leaves arose from an accumulation of solutes.[5,6]

Osmotic adjustment has now been shown to occur in the leaves of many species[7–10] and has also been observed to occur in roots and fruits.[10–12] Additionally, osmotic adjustment in leaves has been shown to vary among genotypes in a range of species.[13,14] Yield benefits associated with osmotic adjustment[13,14] have led to the suggestion that osmotic adjustment is a desirable trait for turgor maintenance at low water potentials.[15] In cereals, osmotic adjustment appears to be under the control of a single gene for osmotic adjustment in wheat.[16,17] However, to date the only crop in which the gene for osmotic adjustment has been used by breeders is wheat, where a cultivar incorporating the gene for osmotic adjustment has been released in Australia.

BENEFITS OF OSMOTIC ADJUSTMENT

Osmotic adjustment is important because it aids in the maintenance of the turgor pressure of the plant as water deficits develop.[7] As growth is a turgor-dependent process, maintenance of turgor is important in maintaining growth.[3] Osmotic adjustment has been shown to maintain photosynthesis and stomatal conductance, defer leaf rolling and leaf death, and maintain root growth to lower water potentials.[13] In turn, this has been shown to induce root growth into deeper soil layers and increase water uptake.[13]

Osmotic adjustment does not necessarily maintain full turgor. Partial turgor maintenance has been documented in a number of species[7] and leads to zero turgor being reached at lower water potentials than when no osmotic adjustment occurs, but at higher water potentials than in the case of full turgor maintenance (Fig. 1). Also, it should be recognized that water potentials below a threshold may decrease before osmotic adjustment is initiated. Jones and Rawson[19] showed that osmotic adjustment reduced the water potential at which the rate of leaf photosynthesis in sorghum reached low values, but did not prevent the decrease in photosynthesis accompanying a decrease in the leaf water potential. Also, chickpea genotypes have been shown to vary in the degree of osmotic adjustment, but this occurred too late into a drying cycle to influence the rate of leaf photosynthesis.[20]

Additionally, the degree of osmotic adjustment is finite. While osmotic adjustment maintains turgor, there appears to be a point beyond which no further solutes accumulate. Further, because the solutes required for osmotic adjustment may also be required during grain filling, it may be undesirable for the solutes accumulated to remain in the leaf. In chickpea, the degree of osmotic adjustment decreased during late seed filling,[20] presumably so that the solutes could be mobilized to the grain.
Indeed, pigeonpea genotypes with high osmotic adjustment toward the end of pod filling had lower yields than those that lost solutes during late pod fill.\[21]\]

Nevertheless, higher yields of wheat, chickpea, and pigeonpea have been associated with greater degrees of osmotic adjustment.\[13,14,21,22]\] In chickpea and pigeonpea, different genotypes were compared, so traits other than osmotic adjustment may have contributed to yield. In wheat, however, comparisons have been made in families selected for differences in osmotic adjustment.\[22]\] In other species, analysis of the benefits to yield of high osmotic adjustment still needs to be undertaken in near-isogenic lines.

**Fig. 1** Schematic representation of the relationship between turgor potential and water potential for (a) full turgor maintenance, (b) partial turgor maintenance, and (c) no turgor maintenance. (Adapted from Ref. 7.)

In order to measure the extent of osmotic adjustment, the change in osmotic pressure induced by the concentration of solutes resulting from water loss needs to be distinguished from the change induced by solute accumulation. To do this, the osmotic pressure at a particular turgor pressure—normally at full turgor—is measured or calculated. To measure or estimate the osmotic pressure at full turgor requires either measurement after rehydration or calculation from measured values of osmotic potential and relative water content (equivalent to the relative osmotic volume in Eq. 1). Because the osmotic pressure at full turgor can change with age and even diurnally, samples from plants subjected to water deficits and those kept adequately watered are taken on the same day, and the degree of osmotic adjustment is considered the difference in osmotic pressure at full turgor between stressed and unstressed plants.

There are errors associated with both of the foregoing methods of measurement. Rehydration may not be complete, or the time required for rehydration may differ between plants that have been stressed to different degrees, so that comparison after the same rehydration time may not be reliable. Also, in some species it is known that solute loss occurs during rehydration, or solutes may be metabolised from osmotically-active solutes to osmotically-inactive solutes—or vice versa—leading to errors in the measurement of osmotic pressure. While such errors in osmotic pressure do not occur when the tissue is not rehydrated, similar errors of rehydration can occur in measured values of relative water content.\[23]\] The osmotic pressure is usually measured by vapor pressure osmometry or freezing-point depression osmometry.\[23]\] However, the osmotic pressure at full turgor can be estimated from pressure/volume relations using the pressure chamber technique.\[24]\] Rehydration is necessary and the rehydration errors discussed above are also relevant with this method. Additionally, the osmotic pressure at full turgor is extrapolated from pressure/volume data below zero turgor, and errors can occur in this range, particularly in tissue that is not woody.\[24]\]

Whether the pressure chamber or osmometry is used to measure the osmotic pressure, the procedures are relatively slow, particularly if watered and unwatered plots are required in order to measure the degree of osmotic adjustment. Where a large number of plants need to be compared, measured values of osmotic pressure and either
relative water content or water potential during a drying cycle have been used to compare the measured values against ones predicted from the concentration of solutes from water loss.\cite{25,26} Fig. 2 shows the changes in osmotic pressure with relative water content and with water potential in nonadjusting and osmotically adjusting plants. (Adapted from Refs. 27,28.)

CONCLUSION

The maintenance of turgor as water deficits develop through the accumulation of solutes is termed osmotic adjustment or osmoregulation and is widely observed in some higher plant species and genotypes. The maintenance of turgor aids in the maintenance of physiological activity, such as photosynthesis and seed growth, and has been shown to benefit crop yields in water-limited environments. The lack of rapid selection methods has hindered the use of the trait in dryland breeding programs, except in the case of wheat, where a cultivar has been developed with high osmotic adjustment. The identification of a marker for osmotic adjustment in wheat and rice should enable the trait to be used in future marker-assisted breeding programs.

INTRODUCTION

Oxygen constitutes 21% of the atmosphere and is the most abundant chemical in and near the earth’s crust. The concentration of oxygen in the atmosphere has risen dramatically since the beginning of life due to the evolution of oxygen during photosynthesis. Because of its chemical properties as an electron acceptor whereby each molecule of dioxygen can accept four electrons producing water, oxygen is fundamentally essential for energy metabolism and respiration in the predominantly aerobic modern biosphere. However, if the gradual reduction process that proceeds by a consecutive addition of electrons is not complete, the partially reduced dioxygen forms highly reactive molecules (Fig. 1). Collectively these molecules are termed reactive oxygen species (ROS) or intermediates (ROI).

The continuous flow of electrons in the cell—especially but not exclusively in the energy producing organelles such as mitochondria or chloroplasts—creates a constant leakage of electrons to oxygen, forming superoxide and other ROS derivatives. The leakage of electrons to oxygen is exacerbated during stresses, invoking a complex array of plant responses.

To counteract the potentially dangerous reactions of the oxidants, organisms have evolved elaborate detoxifying systems. Due to the high internal oxygen concentration and the generation of high-energy electrons by photo-activation, plants are particularly prone to damage by the ROS, and have therefore developed effective antioxidant systems.[1]

The major natural as well as anthropogenic environmental factors that cause damage to living organisms arise from pollution of water, soil, and air, and from solar (UV) and ionizing radiations. These conditions cause ROS accumulation and oxidative stress. In addition, ROS are produced during upward or downward shifts in the surrounding temperature, especially when coupled with strong light.

FORMATION OF OXYGEN RADICALS AND ANTIOXIDANT DEFENSES

ROS formation is part of normal cellular metabolism. For example, O$_2^-$ and H$_2$O$_2$ are the by-products of enzymatic reactions in nucleotide and sugar metabolism. However, the majority of ROS in nonpathogenic conditions are produced by leakage of electrons from the electron transport chains in mitochondria, chloroplasts, and even in the plasma membrane.[2] Another major source of ROS in plant cells occurs in response to pathogen attack and to mechanical stress, which activate the plasma membrane-localized NADPH oxidase.[3,4] A cell wall peroxidase was also implicated in pathogen-induced generation of ROS.[5] These mechanisms of ROS production are not mutually exclusive.

Plants and other organisms possess elaborate systems to detoxify ROS. However, during environmental stress the rate of ROS production can exceed the rate of their removal.[6] Plants possess ROS-detoxifying enzymes that are also found in animals and other organisms, as well as numerous small-molecule antioxidants (e.g., vitamins C and E) that are products of the secondary metabolism unique to plants. The two systems act in cooperation, whereby the antioxidant molecules react with ROS as a first line of defense and are later regenerated by specific enzymes. Adverse environmental conditions affect the redox metabolism in the cell by interfering with the electron flow in the organelles or with the functioning of the antioxidant systems.

REACTIONS OF OXYGEN RADICALS: DNA DAMAGE AND REPAIR

The initially produced ROS (such as superoxide and hydrogen peroxide) react relatively weakly with the majority of biological molecules. Among their main targets are oxidation of the thiol groups in proteins that can later be reduced back by glutaredoxin or thioredoxin systems. However, O$_2^-$ and H$_2$O$_2$ derivatives (such as hydroxyl radicals) react with many biological substrates at a diffusion-limited rate. The OH damage includes protein oxidation, lipid peroxidation, and formation of DNA adducts and strand breaks. The OH radicals also cause cross-linking of the DNA to DNA-binding proteins, leading to a replication block.

Although the damage caused to proteins and lipids may be repaired by removal of the impaired molecules and
replacement with new ones, such a mechanism is not feasible for DNA because the genetic information must be reproduced precisely. The OH radical reacts with little specificity and can cause mutations in any nucleotide (Fig. 2).

The formation of OH radicals is greatly promoted by Fenton reaction in the presence of heavy metals such as iron, lead, copper, and cadmium. These metals are common soil pollutants. Due to its negative charge, DNA has a high affinity for binding heavy metals, thus promoting hydroxyl radicals’ formation in close proximity to the DNA. The most common form of DNA damage is the OH-mediated formation of 8-hydroxyguanosine, which leads to mutagenesis and DNA strand breaks.[7] Especially problematic are the repair of double strand breaks and of mismatches during replication that result in “fixed” mutations. ROS are also involved in DNA strand breaks caused by UV radiation.[8]

In plants, a particularly high rate of mutation occurs during repair of double strand breaks by direct end-joining as part of a nonhomologous recombination.[8] Increased mutation rate is therefore a direct consequence of abiotic/environmental stresses.[9,10] In accord with this, improved antioxidant defenses and decreased oxygen tension were shown to reduce mutability.[11] Interestingly, overexpression of superoxide dismutase is not always beneficial and can even increase DNA damage via accelerated production of H₂O₂, which promotes formation of OH radicals.[12] Thus, a coordinated antioxidant response that includes specific enzymes as well as small molecule antioxidants is essential for genome stability.

**GENE SELECTION AND DEVELOPMENT**

Evolution depends on genetic variability and subsequent selection of the individuals that are better adapted for the given conditions. In plants, the germ cells differentiate from somatic cells in a process that may take many cycles of mitotic division. Thus, somatic mutations can enter germ cells and be transmitted to the progeny.

Being both sessile and lacking a system that regulates internal temperature, plants are continuously impelled to adapt to changes in their surroundings. Environmental stress results in a reduction of photosynthesis and inhibition of growth, resulting in diminished competitiveness against other members of the same species and against other competitors. Such constantly changing environmental factors constitute a strong selection force. Studies have shown that growth of plants in soils polluted with heavy metals induces phenotypic alterations that stem from stress-dependent mutations.[13] More recently it has been shown that ROS-associated (abiotic) stresses enhance both the rate of recombination and mutagenicity in *Arabidopsis* plants.[14]

**SUMMARY**

The sessile nature of plants makes them particularly sensitive to the surrounding environment. During evolution plants have developed sophisticated mechanisms to sense changes in environmental conditions and adapt to them. Almost all environmental stresses are associated with the accumulation of reactive oxygen species (ROS), resulting in secondary oxidative stress. Some of the ROS (such as the hydroxyl radical), are highly reactive molecules that can damage cellular components such as lipids, proteins, and DNA. Moreover, the DNA adducts promote strand breaks, augmenting the damage. Whereas the damaged lipids and proteins can be replaced by new molecules, the repair of DNA is prone to introduce mistakes and result in mutations. In eukaryotes the nuclear DNA exists in dynamic association with histones, forming chromatin.
During transcription the active chromatin unfolds, allowing access of the transcription machinery, while the inactive chromatin remains compacted. Thus, genes that are active during stress are specifically exposed to attack by the hydroxyl radicals, leading to a higher mutation rate. Any favorable mutation that will reduce the primary stress will decrease the oxidative stress and stabilize the genome.

CONCLUSION

Changes in environmental conditions invoke an oxidative stress in plant cells. The reactive oxygen species that are generated during stress react with the cellular components. Particularly damaging is the formation of the hydroxyl radical, which reacts with DNA. In addition to causing direct mutations, DNA adducts produce strand breaks resulting in additional mutagenicity through non-homologous recombination\([8,9]\). The open state of the transcribed genes\([15]\) makes them particularly prone to oxidative damage. Thus, the genes that are expressed during environmental stresses associated with ROS accumulation undergo an increased mutation rate. Improvements in resistance to primary environmental stress by favorable mutations also decrease the oxidative stress and matagenicity, stabilizing plant adaptation to the surrounding environment.

Oxygen Production

Charles F. Yocum
University of Michigan, Ann Arbor, Michigan, U.S.A.

INTRODUCTION

The ability to oxidize water to oxygen is a unique property of the metabolism of oxygenic photosynthetic organisms. An enzyme complex called photosystem II, which is a component of the thylakoid membranes found in chloroplasts of eukaryotes and in cyanobacteria, catalyzes the reaction. The driving force for oxygen production from water is light absorption by photosynthetic pigments. The absorbed energy causes a special pair of chlorophyll molecules (called P680) to release electrons that are ultimately used to reduce CO2 to carbohydrate. Electron deficient, oxidized P680 regains electrons by oxidizing manganese atoms that are part of the active site of oxygen production. This site contains four atoms of manganese, as well as one atom each of calcium and chloride. Although the specific details of the mechanism of the oxygen-evolving reaction are still being sought, it is clear that oxidation of the manganese atoms in photosystem II constitutes the key step in oxygen production. Calcium may bind water molecules destined for oxidation by manganese, while chloride is proposed to regulate the oxidation/reduction activity of the manganese atoms.

OXYGENIC PHOTOSYNTHESIS

Oxygenic photosynthesis is the process by which light energy is converted into chemical energy, and oxygen is released as a byproduct.[1] Light-driven electron transfer reactions are localized in the stacked layers of membranes—called thylakoids—of chloroplasts and cyanobacteria. The ultimate electron source is water, which is oxidized to oxygen. This reaction is presented in Eq. 1, which shows that a key step in the process is absorption of light by an enzyme system called photosystem II. The electrons that are withdrawn from water reduce a quinone molecule called plastoquinone, abbreviated as PQ in the equation. Subsequent oxidation of PQH2 is accomplished by cytochromes and a second light reaction—called photosystem I—that are also found in all organisms that carry out oxygenic photosynthesis.[1]

\[
2\text{H}_2\text{O} + 2\text{PQ}_{\text{OXIDIZED}} + 4\text{photons}(h\nu) \xrightarrow{\text{Photosystem II}} \text{O}_2 + 2\text{PQH}_2
\]  

PHOTOSYSTEM II AND THE S-STATE CYCLE FOR OXYGEN PRODUCTION

Oxygen production by photosystem II is catalyzed by a linear sequence of reactions.[2] Detection of oxygen produced by illuminating a sample with very short (~10 μs) light flashes gives the result shown graphically in Fig. 1. Upon excitation by three sequential flashes, photosystem II emits a gush of oxygen, and does so again on the seventh and eleventh flashes in a series, although the oscillations become less pronounced with larger numbers of flashes. This oscillating pattern is modeled on a cycle containing intermediate states of the oxygen-producing reaction, called S states.[2] Each state is numbered, Si (i = 0–4), and a flash of light advances the S-state system from Si to Si+1. The S-state hypothesis is represented schematically by Eq. 2, where h\nu is used to signify the individual flashes of light.

\[
\begin{align*}
2\text{H}_2\text{O} + S_0 & \xrightarrow{h\nu} S_1 \xrightarrow{h\nu} S_2 \xrightarrow{h\nu} S_3 \xrightarrow{h\nu} S_4 \xrightarrow{h\nu} S_0 \\
+ \text{O}_2 + 4\text{H}^+ + 4\text{e}^- & \quad (2)
\end{align*}
\]

To explain the burst of oxygen on the third flash of light, it has been necessary to postulate that the S1 state is stable in darkness, and this hypothesis is widely accepted. Higher S states can be deactivated to S1 by imposing darkness on the system after one or two flashes of light. Typical lifetimes of S2 and S3 are about one minute. The gradual loss of the oscillating pattern of oxygen release is due to the intrinsic behavior of the enzyme system, which leads to a random distribution of S states after a large number of light flashes or after exposure of the enzyme to continuous light.

LIGHT-DRIVEN ELECTRON TRANSFER REACTIONS

Advancement of S states requires a series of reactions that are initiated by light. The membrane-associated proteins of photosystem II bind the necessary organic cofactors,
which include tyrosines, chlorophylls, pheophytin (a chlorophyll \( \alpha \) molecule lacking the central \( \text{Mg}^{2+} \) atom), and plastoquinone molecules called \( Q_A \) and \( Q_B \).\(^3\) Four atoms of manganese and one atom each of calcium and chloride are also bound to the membrane-associated proteins of photosystem II, to form the active site for oxygen production. Additional water soluble proteins assist in stabilizing the binding of these inorganic ions. A 3.8 Å resolution crystal structure of the enzyme is available,\(^4\) which shows the arrangement of the various cofactors that are involved in light-driven electron transfer and oxygen production.

\end{align*}
\]

Fig. 1  Oxygen yield from photosystem II as a function of the number of light flashes. The maximum yields of oxygen are obtained on the third, seventh, and eleventh flashes. (See text for details.)

Fig. 2  A schematic representation of the electron transfer reactions in photosystem II that precede oxygen production. \textbf{Boldface} type identifies the chemically reactive species at each step in the reaction sequences. (The electron transfer species are identified in text.)
The sequence of electron transfer events that lead to oxygen production is shown in Fig. 2. Light absorption by a special pair of chlorophyll \( a \) molecules, called P680 after the wavelength of light (680 nm) that it absorbs, triggers a cascade of chemical reactions. The excited chlorophyll molecule created by light absorption in Reaction 1 ([P680]\(^{+}\)) is very reactive, and within a few picoseconds (\( \sim 10^{-12} \) s) loses an electron to the acceptor pheophytin molecule, forming [Pheophytin]\(^{-}\), as shown in Reaction 2. Oxidized P680 ([P680]\(^{+}\)) is also very reactive, and removes an electron from a tyrosine residue, called tyrosine Z, forming a radical [Tyrosine Z]\(^{+}\) (Reaction 3). Tyrosine Z is one of the amino acids in the sequence of a membrane-associated protein of photosystem II called D1. In a second part of Reaction 3, [Pheophytin]\(^{-}\) passes its electron on to the first special quinone molecule, to form Q\(_{A}\). The formation of two stable products is shown in Reaction 4. First, the electron removed from P680 by light absorption reduces a plastoquinone molecule called Q\(_{B}\) to form Q\(_{B}\)\(^{-}\). Second, an electron is removed from a manganese atom that is part of the group of inorganic ions that make up the active site of the enzyme, forming [4 Mn/Ca\(^{2+}\)/Cl\(^{-}\)]\(^{+}\). As a result, the energy of the photon absorbed by P680 now resides in two stable species; in a reducing agent, Q\(_{B}\)\(^{-}\), that forms PQH\(_{2}\) after accepting another electron and binding two H\(^{+}\); and in an oxidizing agent, an electron deficient manganese ion. The lifetimes of these species enable them to carry out chemical reactions.

**ROLES OF MANGANESE, CALCIUM, AND CHLORIDE IN OXYGEN PRODUCTION**

In the dark stable S\(_{1}\) state, the oxidation states of the four manganese atoms have been determined to be Mn\(^{3+}\)/Mn\(^{3+}\)/Mn\(^{4+}\)/Mn\(^{4+}\).\(^{[5]}\) Physical techniques for assessing oxidation state changes in these metals indicate that a Mn\(^{3+}\) is oxidized to Mn\(^{4+}\) on advancement of the S states from S\(_{1}\) to S\(_{2}\), and from S\(_{2}\) to S\(_{3}\). The oxidation state of S\(_{4}\) has not been determined, but that of S\(_{0}\) is currently believed to be Mn\(^{2+}\)/Mn\(^{3+}\)/Mn\(^{4+}\)/Mn\(^{4+}\). Removal of either Ca\(^{2+}\) or Cl\(^{-}\) from photosystem II inhibits the S-state cycle after formation of S\(_{2}\). Proposals that calcium may act as a binding site for the water molecules that are oxidized by photosystem II and that Cl\(^{-}\) is present to regulate the oxidation/reduction properties of the manganese atoms\(^{[6]}\) may be relevant in explaining why these ions are needed to advance beyond S\(_{2}\).

The most important question that remains to be answered about photosystem II is how oxidized manganese atoms regain electrons by reacting with water to produce oxygen. One possibility is that an electron deficiency first accumulates among the manganese atoms, after which these atoms regain electrons by oxidizing water to oxygen in a single step. In this mechanism, the manganese atoms would function as a charge accumulator.\(^{[7]}\) In the second hypothetical mechanism, water molecules bind to manganese and undergo partial oxidation as the S states advance. In this mechanism, the sequential removal of electrons from water would permit manganese atoms to undergo oxidation, but there would be no accumulation of charge on the system because neutral hydrogen atoms (H\(^{+}\)) rather than electrons would be transferred.\(^{[8]}\) There is insufficient evidence at present to choose a correct mechanism, and the possibility must remain open that a hybrid system, combining features of both types of hypothetical mechanisms, is responsible for oxygen production.

**CONCLUSION**

Photosystem II extracts electrons from water to form oxygen by carrying out a highly organized set of reactions. Light absorption by chlorophyll initiates a set of electron transfer reactions. These reactions produce two results. The first of these is formation of reduced quinone molecules that shuttle electrons to other components of the photosynthetic electron transfer apparatus. The second consequence of light absorption is that electrons are withdrawn from a cluster of inorganic ions; loss of four electrons results in oxygen production from two water molecules. The reaction is catalyzed by manganese ions, but requires calcium and chloride as well. The precise mechanism for oxidation of water is unknown, but current models favor either charge accumulation by oxidation of manganese followed by water oxidation, or a sequential oxidation of water by abstraction of hydrogen atoms.

INTRODUCTION

Non-wood crops and specialty fiber sources have been utilized for thousands of years in papermaking and other pulp applications. Their use greatly predates that of wood, which now composes about 90% of the worldwide production. As early as the late 1920s in the United States, a mill for producing corrugating medium based on straw began operation. Other mills followed in the Midwest, some of which operated throughout World War II. Unfortunately, they succumbed to high collection, transportation, and storage costs, and to prolonged use of outdated pulping equipment and processes.

Straw, sugarcane bagasse, and bamboo are the leading agricultural fiber sources presently used. China and India, both wood-poor countries, are the main users of straw and bamboo. Several countries use only non-wood fiber resources for papermaking. However, there exists a largely untapped and vast worldwide inventory of these three, plus other crop residues. Additionally, many plant species are suitable for pulping applications. A few, such as kenaf and sunn hemp, have been grown successfully and hence have the potential to add to the overall fiber inventory.

CROP RESIDUES FOR PULPING

Cereal Grain and Flax Straws

By using grain production, the amount of associated straw can be estimated. Data about the 2001 U.S. crop harvest[1] were used to estimate the straw yields for barley, oats, proso millet, rice, rye, and wheat. This computation resulted in an estimated 100 million metric tons (mt) that could be utilized in pulping applications. Most of the straw is either plowed under or used for feed and bedding. On a worldwide basis, the estimate for production of cereal and flax straws is 1.26 billion mt.[2] Straw represents the largest potential supply of crop residues suitable for pulping. The straw from most of the flaxseed oil production in the United States and Canada is processed into high-quality paper products.

Straw from Grass Seed Production

The primary region for grass seed production in the United States is in the tristate area of Oregon, Idaho, and Washington, but is concentrated in the Willamette Valley of Oregon [Banowetz, G.M. Personal communication, U.S. Department of Agriculture; Agricultural Research Service (USDA-ARS): Corvallis, OR, 2002]. The involved grass species include most of the commonly grown lawn grasses and certain types of forage. The resultant straw from about 202,000 hectares (ha) amounts to about 1.4 million mt based on a yield of 6.7 mt per ha. None of this straw is utilized for pulping purposes. About 85% is baled and exported; the remainder is either burned or chopped and plowed under. Future plans include retooling a facility for pulping grass straw.

Stalks from Corn, Sorghum, and Cotton

These crops are widely grown worldwide and their residues are suitable for many pulping applications.[2] Corn and sorghum stalks and the residue of cotton stalks, lint, and linters appear well suited for bleached pulp and corrugating medium. In 2001 in the United States, 27.8 million ha of corn, 3.3 million ha of sorghum, and 5.6 million ha of cotton were harvested.

Sugarcane Bagasse

Bagasse, the residue from sugar-extracted stalks of sugarcane, has long been recognized for its excellent fiber qualities for various grades of paper and board-type applications. Three Louisiana companies have utilized bagasse: One has produced insulator board since the 1920s, another produces a pressed board, and the third (now out of business) produced writing and printing paper for many years.a The case for bagasse is unique in that the use for pulping competes with the use for fuel to power the

aLegendre, B.L. Personal communication, Louisiana State University; Sugar Research Station: St. Gabriel, LA, 2002.
sugar mill. The long-range prospect for increasing use of bagasse is promising because of the large worldwide inventory and the availability of superior harvesting, storage, and pulping equipment plus improved processes (Fig. 1). Crop estimates indicate that the 2001 U.S. harvest of 416,510 ha\(^1\) potentially resulted in 31.6 million mt of stalks (fresh weight basis).

**STEM/CULM FIBER CROPS**

**Bamboo**

There are many species of bamboo, ranging from the large, very tall, tropical types to the small, shrubby, hardier running types. All are perennial with woody culms (stems). Natural stands or groves, especially of tropical species, occur in many countries and could be exploited for pulping purposes. In more temperate countries, the running species of the genus *Phyllostachys* are fairly hardy and amendable to agricultural practices. Strip and rotational harvests help maintain the long-term productivity of the groves. India and China lead the world in bamboo pulping capacity.

**Kenaf and Other Stem Fiber Sources**

Kenaf, an old-world fiber crop, was best known as a jute substitute until identified as having good pulping characteristics. American interest in kenaf arose during World War II as imports of jute and allied fibers for maritime uses became jeopardized. In the early 1960s, research emphasis shifted from use for cordage to papermaking. A member of the mallow family, kenaf is a relative of roselle, okra, flowering hibiscus, and cotton. The stalk is composed of outer bast fibers about 2.6 millimeters (mm) in length and an inner thick core of short fibers about 0.6 mm in length.

Kenaf has been grown successfully in many U.S. states on an experimental and semicommercial or larger scale in about a dozen states. Based on scattered reports, about 4000 and 1500 ha were planted during 2000 and 2001, respectively.\(^b\)

Innovative uses for the bast and core fibers—singularly or in blends—including newsprint (Fig. 2), various papers, absorbents, chicken and small-pet litter, soil amendments, 

---

\(^b\)Columbus, E.P. Personal communication, USDA-ARS: Mississippi State, MS, 2002; Taylor, C. Personal communication, Kenaf Industries of South Texas L.P.: Raymondville, TX, 2002; Sij, J. Personal communication, Texas A&M University: Vernon, TX, 2002.
seeding, and erosion mats, etc. Decorticating systems have been developed to efficiently separate the bast and core fibers. One U.S. company produces papers consisting of about 80% bast and 20% core fibers. The diversity of products manufactured from these fibers should accelerate wider use of kenaf in the future.

The fiber characteristics of roselle and sunn hemp are similar to those of kenaf, but field yields of dry stalks are usually lower. These two crops are apparently immune to root knot nematodes, a kenaf nemesis. Kenaf (a diploid) and roselle (a hexaploid) can be crossed with difficulty. As a legume, sunn hemp production enriches soil through nitrogen fixation. Intense breeding to improve yield and stalk strength in sunn hemp would greatly enhance its potential to become a bona fide fiber crop in the United States. These three fiber sources are photosensitive, thereby requiring short days for floral initiation. Most plantings for seed production are made much later than for fiber. Late planting and lower seeding rates result in short, branched plants that are better suited for machine harvest.

Some other old-world fiber crops that are similar to kenaf in growth habit include hemp, jute, and ramie. Many recall having used jute string or rope. All of these crops are annuals except ramie, a perennial that contains very long fibers. Statistical production and fiber data often lump these four crops with kenaf.

Miscellaneous Fiber Sources

Many plant species are either harvested from natural stands or cultivated for fiber. Most of these are relatively unknown in the Western Hemisphere. The use of these specialty fiber sources, particularly those containing leaf and fruit fibers, is traditionally labor-intensive, thereby tending to keep production low. Sources of these fiber types include leaf-abaca (manila hemp), henequen, maguey and sisal; fruit-coir and kapok; stem-reeds; and whole plants (esparto, papyrus and sabai grass).

CONCLUSION

A great diversity of fibrous plant species with variable fiber characteristics is suitable and potentially available for producing a wide range of pulp-related products. Specific uses have been identified to take advantage of fiber differences. In terms of quantity, the cereal straws, corn and sorghum stalks, and bagasse are predominant.

As the worldwide economic downturn and current recession in the pulp and paper industry eases, greater use of more diverse fibrous raw materials can be anticipated. The most immediate expansion will likely include cereal straws, bagasse, and bamboo. New fiber resources such as kenaf will gradually add to the base supply. Refs. 2 and 3 contain more detailed information about fibrous resources, U.S. and worldwide inventories, and end uses.

Parasitic Weeds

James H. Westwood
Virginia Tech, Blacksburg, Virginia, U.S.A.

INTRODUCTION

Parasitic plants acquire all or part of their nutrition through direct connections to a host plant. Parasitic weeds attack economically important crops and severely reduce crop yield and quality. The most destructive parasitic weeds are mistletoes, dodders, witchweeds, and broomrapes. Control of parasitic weeds is especially difficult because the parasites are closely associated with the host plant, even to the point of being largely concealed within the body of the host (e.g., mistletoes) or hidden underground for a significant part of their life cycle (e.g., broomrapes and witchweeds). The general biology and control of these organisms will be considered.

WHAT ARE PARASITIC WEEDS?

Some plant species have evolved the ability to obtain nutrients from other plants rather than rely on their own roots and photosynthetic systems (Fig. 1). Over 1% of plant species are parasitic, and parasitism has evolved multiple times, with 18 botanical families including parasitic members.[1] The multiple evolutionary origins of parasitism account in part for the large diversity among parasite species in growth form, host preference, and reproductive strategy, but they all tend to be highly specialized and may lack leaves, roots, and the ability to photosynthesize. An important characteristic in categorizing parasitic plants is the level of dependency on the host. Some are facultative parasites, and opportunistically parasitize neighboring plants while retaining an ability to live independently. Obligate parasites, in contrast, have an absolute requirement for a host to complete their life cycles. Obligate parasites are further divided into hemiparasites, which are capable of some photosynthesis, and holoparasites, which lack any photosynthetic capacity and must derive all nutrients from the host.

Parasitic plants that use economically important crops as hosts are among the most destructive weeds.[2] Unlike nonparasitic weeds, which merely compete with crops for resources such as light, water, and nutrients, parasitic weeds tap directly into the crop, removing resources and altering host physiology. Parasitic plants connect to their hosts through a specialized structure, called the haustorium, which penetrates the host and forms a physiological bridge between the two plants. The haustorium serves as a conduit for the removal of water, minerals, and photosynthates from the host, thereby draining it of resources it needs to grow and reproduce.[3] In addition to nutrient acquisition, parasite consumption of host water may cause the host to experience drought when environmental water levels are not limiting. The resulting water conservation efforts by the host only serve to suppress its own photosynthesis and arrest growth. Parasites may also disrupt hormone balance in the host, causing deformities and reallocation of resources away from shoots and fruits.

CLASSES OF IMPORTANT PARASITIC WEEDS

Relatively few species of parasitic plants cause most of the problems to agriculture. Three groups that account for the most destructive parasitic weeds are the mistletoes, dodders, and members of the Orobanchaceae, including broomrapes and witchweeds (Table 1). These parasites are quite different from each other, with distinct morphology and parasitic habits.

Mistletoes

The mistletoes are parasites of the shoots of trees and may grow invasively within the tissues of the host as well as externally. After host penetration, a parasite may grow within the host for as long as four years before emerging. Depending on the species of parasite, the shoots may have leaves that are broad (commonly termed leafy mistletoes) or scale-like (dwarf mistletoes) (Fig. 1A–C). Mistletoes are capable of photosynthesis and are generally green in color. Mistletoes may cause a problem in fruit trees and a wide range of deciduous trees, but the greatest economic impact is in coniferous forests parasitized by dwarf mistletoes. This is a major problem for the lumber industry, and several species of dwarf mistletoe decrease timber growth and quality, accelerate incidence of other diseases, and even kill trees. Mistletoes are found worldwide and the value in timber lost on an annual basis in North America alone is estimated to exceed several billion dollars.[4]
Dodders

Dodders are vining parasites that attack the stems and leaves of their hosts (Fig. 1D). These parasites consist of tendril-like stems that wrap around the host and form haustoria at points of contact, with each connection fueling further growth to find additional host shoots. In this way, dense mats of dodder may be formed that simultaneously parasitize many host plants. Although most species of dodder have functional photosynthetic systems, they are generally yellow in color and rely heavily on hosts for resources.\(^2\) Dodders can be very destructive, greatly reducing yields of parasitized crops, and can also be mildly toxic to livestock if consumed with infested forage. Dodders occur throughout the world and affect a wide range of woody and herbaceous dicotyledonous plants.

Broomrapes and Witchweeds

Broomrapes and witchweeds both parasitize plant roots, but while broomrapes are holoparasites that lack photosynthesis and developed leaves, witchweeds have green leaves and the capacity for photosynthesis after emergence from the soil (Fig. 1E–F). The tiny seeds of these parasites lie dormant in the soil until stimulated to germinate by chemical signals exuded from host roots. The haustorium is produced from the parasite radicle as it nears contact with a host root. Once the parasite has established connections to the host, it can grow. Whereas broomrapes develop a bulbous structure adjacent to the host root, witchweed initiates a vegetative shoot that grows out of the soil. The impact of these parasites on their hosts can be dramatic, with estimates ranging from partial to complete yield loss, depending on environmental conditions and level of infestation.\(^2\) Both species flower above-ground and may produce hundreds of thousands of seeds per plant. If measures are not taken to reduce the levels of infestations, seeds of these weeds can build up in the soil to the point that farmers must rotate to non-host crops or abandon the fields completely. These species present the greatest problems in the arid tropics, although their ranges are not restricted to these areas. Witchweeds are centered in Africa and India, while
broomrapes occur commonly in regions around the Mediterranean, Middle East, and Eastern Europe.

**CONTROL OF PARASITIC WEEDS**

Parasitic weeds are extremely difficult to control. Their connection to the host plant makes physical removal nearly impossible. For example, removal of mistletoe shoots or mistletoe-infected branches is common, but does not prevent subsequent regrowth from parasite tissue embedded in the host. Dodder is similarly problematic since the stem is tightly wrapped around and connected to the host, and pulling does not remove all tissue. Witchweed and broomrape are both concealed beneath the ground during the crucial early stages of their life, and are thus hidden from sight and from mechanical control measures.

Chemical control strategies are also challenging because of the close association of host and parasite. With the exception of dodder seedlings, which germinate in the soil and are susceptible to certain pre-emergent herbicides, problems of herbicide delivery and selectivity prevent easy control of parasites.[5] While innovations in herbicide formulation and delivery enable some herbicides to be used effectively, the development of crops with resistance to translocated herbicides such as glyphosate holds promise for parasitic weed control.[6] However, until such crops are widely available, soil fumigation (e.g., methyl bromide) remains the most effective chemical control against root parasites. Soil injection of ethylene gas induces germination of witchweed seeds in the absence of a host (termed “suicidal” germination because the parasite cannot survive without a host present) and can be effective where economics justify the high expense.

Cultural practices can reduce parasite populations. Rotations including nonhost crops disrupt the cycle of parasitism. Also, altering planting dates, improving soil fertility, and intercropping have been used to reduce witchweed and broomrape damage. For mistletoes, the selective removal of infected trees and maintenance of distance between trees can reduce spread. Breeding for

(Information from Refs. 2, 4, 5, and 7.)
parasite-resistant crop varieties has received considerable attention and is an ideal solution to the problem, although currently few durably resistant varieties are available for most affected crops. Considering the difficulty in controlling parasitic weeds, preventive practices are important in stopping the spread of parasite seeds to new areas and limiting reproduction where parasites populations are low.

FUTURE DIRECTIONS

Important areas of future research for parasitic weed control include mechanisms of host detection by the parasite, parasite-environment interactions, biological control, and development of resistant host crops. Ironically, it is possible that the close relationship between host and parasite that makes them so difficult to control may lead to new ways to protect crops. This has already been illustrated by the chemical control strategy mentioned above, in which lethal doses of herbicide are delivered to attached parasites via translocation through crops that have been engineered to resist the herbicide.[6] A more direct strategy, requiring no chemical input, is to engineer host crops that are able to prevent parasite attachment and growth at the earliest stages of infection. This may harness the host’s own pathogen defense machinery (e.g., phytoalexins or hypersensitive response) or may use entirely novel mechanisms to disrupt parasite growth. Greater understanding of parasitic weeds, including their physiology and host interactions, will facilitate the development of new parasite-resistant crops.

ACKNOWLEDGMENTS

Dan Nickrent and the Parasitic Plant Connection[7] were very helpful in finding photographs of parasitic weeds. Thanks also to Brenda Winkel for critical reading of the manuscript. Pharmaceutical Overproduction and Purification of Biopharmaceuticals Through His-Tagged GUS Fusion Expressions in Chloroplasts

Vanga Siva Reddy
Sadhu Leelavathi
International Center for Genetic Engineering and Biotechnology, New Delhi, India

INTRODUCTION

Transgenic plants offer an excellent expression system to produce foreign proteins useful in the pharmaceutical industry in bulk quantities at low costs. High-level expression and efficient recovery of recombinant protein at low costs are two critical factors that determine the use of transgenic plants as natural bioreactors. A number of proteins/peptides that are highly useful in the pharmaceutical industry are currently being expressed in plants. So far, most of these proteins were expressed through nuclear integration of transgenes—a method that has been well established for a number of plant species. However, the nuclear transformation method has several limitations, the most important being the low-level expression of foreign genes in transgenic plants. This disadvantage can be overcome by integrating transgenes into the chloroplast genome.

CHLOROPLASTS IN PLANTS

Majority of biopharmaceuticals that have been expressed in plants through nuclear transformation can also be expressed through chloroplast transformation where a very high level of expression can be reached as plant cells contain 50–100 chloroplasts per cell, and each chloroplast contains multiple copies (50–100) of the plastid genome. When a foreign gene is transformed and integrated into the chloroplast genome, it results in high-level expression, which is 100-fold to 500-fold higher when compared with the same gene transformed into nuclear genome. Furthermore, unlike in nuclear transformation where a transgene normally integrates randomly in the genome, the foreign gene can be integrated at a predetermined site in the chloroplast genome through recombination based on homology, thus promoting uniformity of expression in independently transformed plants. Furthermore, chloroplasts in most crop species are maternally inherited; therefore, this approach reduces the risk of transgene transfer to related species through pollen. Another possibility with plastid transformation is the ability to modify metabolic pathways that are chloroplast-encoded, including photosynthesis.

PLASTID TRANSFORMATION

Typically, a chloroplast transformation vector contains a small plastome (chloroplast genome) of intergenic DNA flanking the transgenes for their site-specific integration, and transgenes are linked to regulatory DNA sequences (promoters and terminators) derived from the genes coded by the plastid genome to drive their expression. To isolate transformed cells and eventually regenerate a complete transformed plant, a selectable marker gene, usually aminoglycoside adenine transferase (aadA), which confers resistance to spectinomycin/streptomycin, is also placed in the vector next to the transgene of interest. When such vector DNA is delivered into plant cells via a gene gun (an apparatus that is used to bombard the target tissue with vector DNA coated onto tungsten/gold particles; Fig. 1), transgenes are integrated into the plastome through two possible homologous recombinations between flanking regions provided in the vector and the endogenous plastome (Fig. 2). Transformed cells/plantlets are obtained after continuous selection on the nutrient medium containing spectinomycin (Fig. 1). Following such a technique, a number of foreign genes have been transformed into tobacco chloroplasts and their expression has been studied in detail.

BACILLUS THURINGIENSI S TRANSGENIC PLANTS

The Bacillus thuringiensis (Bt), a soil bacterium, produces crystal toxins that are considered to be safe as biological insecticides. Transgenic crop plants that are resistant to insects have been developed through the genetic transformation of Bt genes. Production of effective levels of these
proteins in plants required resynthesis of the genes encoding them. Stable integration of an unmodified cry1A(c) gene into the plastid genome was shown to amplify the copy number of Bt gene in chloroplasts producing high levels of insecticidal protein.[18] Another Bt protein, Cry2Aa2, was also shown to overexpress when transformed into a plastid genome, reaching up to 2–3% of the total soluble protein (TSP).[19] Later, the same group reported the accumulation of Cry2Aa2 at a very high level (45.3% of TSP) when an operon containing a putative chaperon along with the Bt gene was transformed into chloroplast.[20] This was the highest level of expression reported for any foreign protein in plants so far.

CONTAINMENT OF TRANSGENE SPREAD TO WILD-RELATED SPECIES

The potential of transgene transfer from transgenic plant to related plant species through pollen is currently a major environmental concern that limits the widespread acceptance of genetically modified (GM) crops. As plastid genome is inherited maternally in the majority of crop plants, the introduction of foreign genes into the chloroplast genome may be an alternative approach to contain transgene spread to wild relatives through cross-pollination. Svab and Maliga[17] demonstrated the maternal inheritance of a selectable marker gene (aadA) used to transform tobacco plastids. Later, Daniell et al.[21] demonstrated the maternal inheritance of a plastid-integrated transgene from petunia coding for an enzyme 5-enol-pyruvyl shikimate-3-phosphate synthase (EPSPS) that confers resistance to a potent herbicide.

CHLOROPLAST GENETIC ENGINEERING FOR PHYTOREmediATION

Chloroplast genetic engineering was also used to enhance the capacity of plants for phytoremediation. The organic form of mercury (Hg) is a highly toxic pollutant affecting both plants and animals. Tobacco plants engineered to
overexpress mercuric ion reductase (merA) and organomericurial lyase (merB) as an operon in chloroplasts were shown to tolerate the presence of high concentrations (even up to 400 mM) of the organomercurial compound, phenylmercuric acetate (PMA), in soil.[22]

VACCINE PRODUCTION

Potentially, chloroplast genetic engineering offers a major advantage over conventional nuclear transformation for the production of biopharmaceuticals in plants due to gene amplification in plastids. Daniell et al.[23] expressed a vaccine candidate gene, the cholera toxin B (CTB) subunit, in tobacco chloroplasts. About 4.1% of TSP was found to be of CTB and the expressed protein assembled into a functional oligomeric form. Similarly, Tregoning et al.[24] achieved the expression of another vaccine candidate gene, fragment C (TetC)—a nontoxic polypeptide fragment of tetanus toxin that can be used as a subunit vaccine against tetanus. Of the two variants of the same gene, they have expressed: 1) a native bacterial AT-rich (72.3% AT) gene, and 2) a synthetic GC-rich gene; the native gene was found to be expressed at high levels (25% of TSP) when compared with the synthetic gene that was expressed at relatively low levels (10% of TSP). This could be due to the fact that the chloroplast genome is AT-rich, similar to bacterial genomes. Mucosal immunization of mice with the plastid-produced TetC was found to induce protective levels of TetC antibodies. In a separate study, Staub et al.[25] have shown the feasibility of the production of a human therapeutic protein, somatotropin, in tobacco chloroplasts. High concentrations of recombinant protein accumulation were observed (7% of TSP) in protein extracts from the leaf tissue. The plastid-produced somatotropin was found to fold correctly with proper disulfide bonds and exhibited biological properties.

BIOPHARMACEUTICAL PRODUCTION

More recent studies have shown that the human interferon γ (IFN-γ), also known as immune interferon,[26] can be produced at high amounts in chloroplasts and the recombinant protein can be recovered efficiently.[27] In this procedure, the IFN-γ gene was fused to a reporter β-glucuronidase gene (uidA or GUS)[28] and a protease (factor Xa) recognition site was placed between IFN-γ and GUS to separate the IFN-γ after purification (Fig. 3). To facilitate the purification of GUS:IFN-γ fusion protein from a large number of plant proteins, a six-histidine amino acid (His tag) coding region was added at the amino terminal region of the fusion protein. The expression of GUS:IFN-γ fusion protein can reach up to 8% of TSP.[27]

EXTRACTION OF RECOMBINANT PROTEINS

Purification of recombinant proteins is potentially an expensive step for the production of biopharmaceutical products in plants. Purification of recombinant IFN-γ was achieved following a three-step procedure (Fig. 4). In the first step, ion exchange chromatography (DE-52) was used to purify partially a fusion protein from a crude plant extract. In the second step, affinity-based chromatography was employed to purify the fusion protein to homogeneity. To achieve this step, a ligand (nickel nitrilotriacetic acid, or Ni-NTA) that has a high affinity to six or more histidine residues at a stretch (His tag) is used to immobilize the recombinant protein. The recombinant protein is engineered to contain the His tag at the amino-terminal end or carboxy-terminal end. When the plant extract containing a recombinant protein with a His tag is passed through the Ni-NTA column, the recombinant protein is retained, whereas plant proteins pass through the column. The recombinant protein is then eluted from the column using imidazole, which has a relatively more affinity toward Ni-NTA. Although His tag and Ni-NTA combination was used to demonstrate the power of affinity chromatography, any other tag with a high binding specificity to a ligand can be used for this purpose. In the third step, the fusion protein is digested with factor Xa to cleave the IFN-γ from the GUS protein and purified further using an S-Sepharose column. The purified IFN-γ protein retained its biological activity.

In molecular biofarming, the recombinant protein must not only be purified, but it should also be purified rapidly as the recombinant protein can be degraded during the purification period due to harsh and lengthy processing conditions. In plants, the afterstep is equally important, as plant cells contain a number of proteases that can potentially degrade the recombinant protein during the purification stage. Identification of a recombinant protein containing fractions during downstream processing by conventional sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), enzyme-linked immunosorbent assay (ELISA), and Western blot analysis is laborious and time-consuming. The uidA (GUS) system is a highly sensitive reporter gene system used extensively to follow the transformation and expression of foreign genes in transgenic plants. One of the key advantages of GUS is its ability to accept both N-terminal and C-terminal fusions without losing enzyme activity. Such a versatile reporter gene system can be extended to recombinant protein purification by simple GUS fusions. The fractions containing a GUS:IFN-γ protein can be identified during the purification process by using a simple and inexpensive GUS assay based on rapid development of color (in less than 5 min). Therefore, the GUS fusion system, combined with chloroplast transformation, offers two key advantages: 1) it increases the yields of low-accumulating and fast-degrading recombinant proteins by providing stability; and 2) it reduces downstream processing time significantly. Therefore, these new strategies have high
Fig. 4 Schematic diagram illustrating various steps involved in the purification of IFN-γ from tobacco leaf tissue. (View this art in color at www.dekker.com.)
potential to convert plants to “natural bioreactors” for the large-scale production of a number of pharmaceutically important proteins/peptides in the near future.

CONCLUSION

Foreign genes are expressed at very high levels in chloroplasts, ranging from 3% to 45% of TSP. The recombinant proteins can be expressed as fusion proteins of GUS, which is very useful in the purification process. The purified recombinant proteins are folded accurately and exhibit their biological functions. Therefore, chloroplast genetic engineering can play a major role in the production of biopharmaceuticals using plants as natural bioreactors.

Pharmaceuticals in Plants

Kazuhito Fujiyama
Osaka University, Osaka, Japan

INTRODUCTION

The potential of production of recombinant proteins in plants represents a new green revolution. Compared to conventional host systems such as Escherichia coli, baculovirus, yeast, and animal cells, plants have many advantages, such as production costs and scale up, safety, multimeric protein assembly, and posttranslational modification. Until now, cytokines, antibodies, hormones, and vaccine proteins have been produced and tested for their efficacy. In particular, antibodies produced in plants will be good examples of the first molecular farming products, because plant-antibodies (plantibodies) have been clinically examined and proven functionally similar to those produced by animal systems.

RECOMBINANT ANTIBODIES

The expression and assembly into functional antibodies of two antibody peptide subunits, heavy and light chains, was demonstrated in transgenic tobacco plants. Since then, full-sized or chimeric IgG, IgM, IgA, and other recombinant antibody forms including heavy-chain variable domains, fragment antigen binding (Fab), and single-chain antibody fragment (scFv) have been produced. Secretary IgA (sIgA) is a remarkable example, because sIgA is a decameric immunoglobulin peptide subunits composed of four α-heavy chains (Hc), four light chains (Lc), a joining chain (J), and a secretary component (Sc). Two immunoglobulin molecules, 2 (2Hc2Lc), are associated with J and Sc. Full size of secretary antibodies were properly assembled in plants, and successfully used for clinical trial. Antibody expression in plants has been also used for other objectives. Expression of antipathogen antibodies conferred more pathogen resistance to plants. In other cases, antibodies produced in plant bound to some compounds, such as substrates or phytohormones, and resulted in the alteration of metabolic pathway or hormone-regulated pathways.

PLANTS

Plants used for antibody factory include tobacco, potato, Petunia, soybean, rice, alfalfa, pea, tomato, corn, and Arabidopsis. Expression levels vary depending on plants, plant tissues, and expression systems including promoter, terminator, and the gene used. In a case of scFv against carcinoembryonic antigen, rice showed 20 times higher expression in seeds than wheat and tobacco, and produced 32.0 µg/g seed, and 29.0 µg/g leaves and 3.8 µg/g callus.

EXPRESSION LEVELS AND SYSTEMS

Transgenic-plant proteins with possible vaccine applications for human and animal showed maximum expression level from <0.01% to 1.00% of total soluble proteins (TSP). In tobacco plants, heat-labile toxin B-subunit was <0.01% of TSP; Norwalk virus capsid proteins, 0.23%; transmissible gastroenteritis coronavirus glycoprotein S, 0.20%. The expression levels of human biopharmaceutical proteins for human health in transgenic tobacco plants were also different; protein C, <0.01% of TSP; serum albumin, 0.02%; hemoglobin α, β, 0.05% of seed protein; glucocerebrosidase, 1.00–10.00%; somatotropin, 7.00% in chloroplast. Generally, however, expression levels of recombinant antibodies in transgenic plants lie between 0.5% and 2% of TSP.

SUBCELLULAR LOCALIZATION

The higher expression of recombinant antibody has been a challenge. Functional full-length antibodies produced in plant are translocated through the cell wall and accumulate in the intercellular space of leaf tissue when no retention signals are present. It has been reported that recombinant antibody yield increased when antibodies were targeted to the secretary pathway, and not produced in the cytosol. Endoplasmic reticulum (ER) retention expression yielded significantly higher level of productivity. Furthermore, localization in the ER avoided plant-specific complex glycosylation and degradation by protease in the secretary pathway and apoplast. Production of scFv fragment in the cytosolic fraction or cytoplasm was very low. Targeting of scFvs toward the apoplast or cytosol resulted in expression level below 0.1%, while scFvs retained at the ER were higher, generally more than 1%. The formation of disulfide
bridges by scFv antibody in the plant cytosol has been recently confirmed.\[9\]

Intracellular organelles used for antibody production were vacuolar and nucleolus.\[1\] Transformation of chloroplast has been shown to accumulate numerous recombinant proteins and facilitate purification procedures.\[10\] It remains unclear if chloroplasts can synthesize recombinant proteins which need complex posttranslational modifications.

PRODUCT STABILITY AND QUALITY

The effect of physiological conditions and developmental-stage was shown to influence antibody production.

For antibody production, climatic condition and developmental stage are important factors. Highlight growth conditions induce better production of biomass, total soluble protein, and antibody. The plants incubated at 25°C grew faster and produced less antibody per amount of leaf tissue than the plants incubated at 15°C.\[11\] Both endogenous protein and antibody content declined remarkably as leaf developed.\[11\]

Like other proteins, functional antibodies produced in plants have been stored in dried leaves, seeds, and tubers.\[1,2\] Expression in seeds can confer not only long life properties of the recombinant proteins, but also more the flexible chance of downstream processing strategy, such as purification.

The stability of antibodies produced in tobacco was examined. A substantial part of the antibody H-subunit was degraded during leaf development. The proteolytic degradation of plantibody H-subunit occurred faster than the H-subunit of antibodies from hybridoma cells. The proteolytic degradation in plants, mainly found in extracellular compartment (apoplast) of shoot and root tissues, and in cytoplasm, resulted from the senescence process.\[5\] However, the antihuman IgG monoclonal antibodies produced in transgenic alfalfa plants were stable in plant extracts.\[12\]

The physiological conditions of the plants themselves should also be taken into consideration for greater production of antibodies with higher quality.

GLYCOSYLATION, IMMUNOGENICITY, AND ALLERGENICITY

Structures of N-linked glycans on plant- and hybridoma-produced antibody have been determined and compared. Plant-antibody carried typical plant glycans with β1,2-xylose and α1,3-fucose residues, but not animal-type sugar residues, such as galactose and sialic acid. The immunogenicity of this plant-produced monoclonal antibody was tested in mice, and results showed that the plant-antibody was not immunogenic.\[13\]

An IgG produced in alfalfa had a serum half-life in mice that was indistinguishable from that of the hybridoma-produced antibody.\[12\]

However, there is some concern about the potential immunogenicity and allergenicity of plantibodies used as human therapeutics.\[12\]

The H-subunit of transgenic-plant antibody showed a higher degradation rate than the hybridoma cells H-subunit.\[11\] The N-linked oligosaccharide on antibody contributed to protein stability. Susceptibility is considered to stem from the fact that plantibodies have plant-typical glycan structures. Thus glycosylation also affects protein stability.

COST

The cost of producing an IgG from alfalfa grown in a 250-m² greenhouse are estimated to be $500–600/g, compared with $5000/g for the hybridoma-produced antibody.\[12\]

FUTURE OF ANTIBODIES PRODUCED IN PLANTS

Recently, the production of more than 100 antibodies has been tried in various plants by using different expression systems. Plant expression systems constitute a promising technology, because it offers numerous advantages compared to other systems. However, glycosylation and productivity are two of the main disadvantages of this technology. Clinical trials of some plant-produced antibodies have been successfully conducted. In the next decade or two, it is projected that this production system will take over conventional production systems.

Phenylpropanoids

Kevin M. Davies
New Zealand Institute for Crop and Food Research Limited, Palmerston North, New Zealand

INTRODUCTION

Plant phenylpropanoids are a major group of secondary metabolites derived from phenylalanine. They have a wide range of functions in plants, both as structural compounds and in interactions with the environment and other organisms. The importance of phenylpropanoids in general biology can be illustrated by a few observations on just one of the phenylpropanoid subgroups, the lignins. Lignins are the second most abundant polymer in plants, after cellulose, and are required for xylem formation and strengthening of cell walls. The evolution of lignin biosynthesis is thought to have been a key step in the colonization of land by plants. Today it is estimated that phenylpropanoids account for over 30% of all organic carbon in the biosphere, and that the majority of this is lignin. Furthermore, the degradation of lignin is a major rate-limiting step in the carbon cycle.

BIOSYNTHESIS AND FUNCTION

The proposed biosynthetic pathway of the major phenylpropanoid groups is represented in Figs. 1 and 2. The initial compounds, hydroxycinnamic acids (HCAs), are formed from phenylalanine by phenylalanine ammonia lyase (PAL), cinnamate 4-hydroxylase (C4H), and 4-coumarate:CoA ligase (4CL). All the other phenylpropanoid types arise from the HCAs. A core section of the phenylpropanoid biosynthetic pathway is common to most plants, including ferns, in particular to the formation of HCAs, flavonoids, lignins, and proanthocyanins (tannins). However, based on these core compounds a huge diversity in structure occurs. For example, about 5000 flavonoid types can arise through glycosylation, hydroxylation and substitution with methyl, sulphur, and aliphatic or aromatic acyl groups. While the functions of the major phenylpropanoid groups are known, the roles of the many variant structures is often unclear. Several excellent in-depth reviews of phenylpropanoid biosynthesis and diversity are available.[1–3]

Lignins and Lignans

Lignins and lignans are polymeric molecules formed by different biosynthetic routes from the same monolignol precursors (Fig. 1). Lignins are high-molecular-weight polymers found in cell walls. Lignans are commonly dimers, although they can form higher oligomers, and are found in abundance in wood resins, in which they may play a plant defence role. Monolignol biosynthesis from the HCAs involves a network of aromatic hydroxylations, NAPH-dependent reductions, CoA ligations, and O-methylations. For lignin biosynthesis, the monolignols are transported from the cytosol to the cell wall, where polymerisation occurs, probably on a proline-rich protein template and catalyzed by peroxidases and laccases. The structures formed can vary much between species, and even within a plant, and the mechanisms that control the process are unclear. However, a dirigent protein was recently characterized that can determine the type of stereospecific coupling linkages that occur between the monolignol precursors.

Flavonoids

The first committed step of flavonoid biosynthesis occurs with the formation of chalcones by chalcone synthase (CHS), when three units of acetate-derived malonyl-CoA combine with the phenylalanine-derived 4-coumaroyl-CoA (Fig. 2). The subsequent steps of flavonoid biosynthesis, resulting in the formation of the anthocyanins, proanthocyanins, flavones, and flavonols, are common to nearly all flowering plants. The notable exception are most species of the Caryophyllales, in which the colored anthocyanins are substituted with betalain pigments. Along with chlorophylls and carotenoids, anthocyanins are major pigments of plants, capable of providing color to all plant tissues. There are three common anthocyanin groups, pelargonodin-derivatives, cyanidin-derivatives and delphinidin-derivates, which usually result in pink-red, red-purple, and mauve-blue colors, respectively. They are typically glycosylated, often further substituted, and localised to the vacuole. However, rare and highly modified anthocyanin forms occur in nature, with over 600 individual anthocyanins reported to date.

Many biosynthetic branches occur in the flavonoid pathway. Of particular note are the action of chalcone reductase (CHR) with CHS forming 6′-deoxychalcones, the aureusidin synthase forming aurones, flavone synthase (FNS) forming flavones, flavanone reductase (FNR)
forming 3-deoxyanthocyanin precursors, flavonol synthase (FLS) forming flavonols, and isoflavone synthase (IFS) forming isoflavone precursors. Many of these enzymes and compounds are taxonomically restricted in their occurrence.

In addition to pigmentation, the functions of flavonoids are diverse. They can protect leaves from oxidative stress and ameliorate the impact of UV-B radiation. They are also key plant defence compounds. The isoflavonoids and flavone C-glycosides are involved in defence against fungal and insect attack, and proanthocyanidins can be herbivore deterrents. The flavonols are essential for fertility in some species, acting by an unknown mechanism during pollen growth in the stigma. Flavonoids are also key signal compounds, most notably to the soil bacterium *Rhizobium*, to trigger nodulation for symbiotic nitrogen fixation. The formation of heartwood in trees is marked by the accumulation of phenylpropanoid rich resins, which are commonly a mix of flavonoids, lignans, and stilbenes. It will be obvious from this list that flavonoids are a key branch of plant secondary metabolism. However, these are probably only some of the functions for these compounds. The action of flavonols in plant fertility came to light only in the early 1990s and, given the great diversity of structural types, many flavonoid functions may yet be determined. For example, there is growing evidence that flavonoids influence auxin transport.

**Coumarins, Stilbenes, and Related Compounds**

In addition to lignins and flavonoids, a range of other compounds are derived from HCAs. Coumarins are a varied group of compounds, widespread in nature, whose primary function appears to be in plant defense. A well
known example of their impact is the photosensitive skin blistering that can result from handling celery (*Apium graveolens*) or giant hogweed (*Heracleum mantegazzianum*). The coumarin biosynthetic pathway(s) have not been elucidated, although it is thought that the initial reactions are cis/trans-isomerisation and ring closure of a HCA. The condensation of malonyl-CoA and HCAs can form compounds other than the flavonoids. A group of CHS-like enzymes use malonyl-CoA and a HCA-CoA to form a range of plant defense compounds. The best characterized are the stilbene synthases (STS) that form compounds such as resveratrol and pinosylvin. Like CHS, they carry out three condensation reactions followed by ring closure, but the nature of the ring closure differs. To date, over 300 different stilbenoid structures have been reported. Malonyl-CoA and HCA-CoA compounds are also the precursors for the arylpyrones and styrylpyrones. These reactions involve only one or two condensations prior to ring closure, but little is known of the biosynthetic enzymes.

**The Molecular Biology of Phenylpropanoid Biosynthesis**

The colored flavonoids have provided model systems for scientists since the time of Mendel’s inheritance studies. More recently, studies on flavonoids have been responsible for some of the most important breakthroughs in plant science, including the cloning of the first plant transcription factor gene, the isolation of one of the first cDNAs for a plant cytochrome P450 enzyme, the first demonstration of antisense RNA technology in a transgenic plant, and the first characterization of a transgene...
cosuppression mechanism. Studies with the major model systems, *Antirrhinum majus*, *Arabidopsis thaliana*, *Petunia*, and *Zea mays*, have resulted in the isolation of cDNAs or genes for most of the core biosynthetic enzymes of phenylpropanoid biosynthesis, and for several transcription factors involved in the regulation of the pathway.\(^{[2,5]}\) Transposon-generated mutations have been key to the successful elucidation of the molecular genetics of phenylpropanoid biosynthesis. A more recent extension of the use of mutants is the linking of metabolic profiling to the genomics systems available for species such as *Arabidopsis* and *Medicago truncatula*.\(^{[6]}\) Research is now focusing on aspects such as the regulation of the biosynthetic genes, the subcellular interactions of the biosynthetic enzymes, the biosynthesis of rare phenylpropanoid types, and the control of lignin formation.

**The Importance of Phenylpropanoids to Agriculture and Human Health**

Phenylpropanoids affect the quality and quantity of the harvested products from most plant crops. Obvious examples include the impacts of lignin and heartwood resins on timber and pulping wood quality, lignin on forage crop digestibility, tannin production for the control of bloat in ruminants, flower and foliage color in ornamental crops, tannin production in wine, and flavor and fragrance compounds in spice crops and teas. Phenylpropanoids are also key plant defense compounds. However, perhaps the area of keenest research interest at present is the influence of phenylpropanoids on human health. Numerous in vitro experiments, animal trials, and epidemiological studies have linked the intake of specific phenylpropanoids with a reduced risk of conditions such as cancer and heart disease. The mechanisms behind such actions are generally unknown, although the antioxidant activity of many phenylpropanoids has often been implicated.

Given the importance of phenylpropanoids in agriculture it is not surprising that the pathway was one of the early targets for genetic modification approaches. Metabolic engineering in transgenic plants has been used to alter the production of nearly all of the different groups of phenylpropanoid compounds.\(^{[7,8]}\) Transgenic carnations with modified flower color through the alteration of anthocyanin biosynthesis are on sale in a number of countries, and it is anticipated that these will be joined by some of the transgenic plant lines currently in field trials, such as trees with improved lignin characteristics, forage crops with improved digestibility, and food crops with high levels of health-promoting phenylpropanoids.

Phosphorus

Carroll P. Vance
USDA/ARS Plant Science Research Unit and University of Minnesota, St. Paul, Minnesota, U.S.A.

INTRODUCTION

Phosphorus (P) is one of 17 essential elements (nutrients) required for plant growth. The P concentration in plants ranges from 0.05 to 0.50% dry weight. It plays a role in a wide array of processes, including energy generation, nucleic acid synthesis, photosynthesis, glycolysis, respiration, membrane synthesis and stability, enzyme activation/inactivation, redox reactions, signaling, carbohydrate metabolism, and nitrogen (N) fixation. The concentration gradient from the soil solution orthophosphate (P_i) to plant cells exceeds 2000-fold, with an average free P_i of 1 μM in the soil solution. This concentration is well below the K_m for plant uptake. Thus, although bound P is quite abundant in many soils, it is largely unavailable for uptake. As such, P is frequently the most limiting element for plant growth and development. Crop yield on 30 to 40% of the world’s arable land is limited by P_i availability. Phosphorus is unavailable because it rapidly forms insoluble complexes with cations, particularly aluminum and iron under acid conditions. The acid-weathered soils of the tropics and subtropics are particularly prone to P_i deficiency. Moreover, some 30 to 70% of the P can be bound in insoluble organic forms (such as phytate) due to microbial activity. Application of P-containing fertilizers is the recommended treatment for enhancing soil P_i availability and stimulating crop yields.

THE PHOSPHORUS CONUNDRUM

Application of P fertilizer, however, is problematic for both the intensive and extensive agriculture of the developed and developing worlds, respectively. In intensive agriculture, a grain crop yield of 7 metric tons Ha^{-1} requires the addition of 90 to 120 kg P·Ha^{-1} (11-31). But even under adequate P fertilization, only 20% or less of that applied is removed in the first year’s growth. This results in P loading of prime agricultural land. Runoff from P-loaded soils is a primary factor in eutrophication and hypoxia of lakes and marine estuaries of the developed world (1,4,5). Another reason for alarm is that by some estimates, inexpensive rock phosphate reserves could be depleted in as little as 60 to 80 years (1,6). Phosphorus fertilizer use increased 4- to 5-fold between 1960 and 2000 and is projected to increase further by 20 Tg·year^{-1} by 2030 (Tables 1-3). Several authors have noted that a potential phosphate crisis looms for agriculture in the 21st century (1,4,6,7). A concern even greater than the overabundant use of P fertilizers by intensive agriculture is the lack of available P fertilizers for extensive agriculture in the tropics and subtropics where the majority of the world’s people live. Lack of fertilizer infrastructure, money for purchase, and transportation make P fertilization unattainable for these areas. Sustainable management of P in agriculture requires that plant biologists discover mechanisms that enhance P_i acquisition and exploit these adaptations to make plants more efficient at acquiring P_i, develop P-efficient germplasm, and advance crop management schemes that increase soil P_i availability.

ADAPTATIONS TO LOW P

Because of its ubiquitous importance, plants have evolved two broad strategies for P acquisition in nutrient-limiting environments: 1) those aimed at conservation of use; and 2) those directed toward enhanced acquisition or uptake (1,8). Processes that conserve the use of P involve decreased growth rate, increased growth per unit of P uptake, remobilization of internal P_i, modifications in carbon metabolism that bypass P-requiring steps, and alternative respiratory pathways (1,8). By comparison, processes that lead to enhanced uptake include increased production and secretion of phosphatases, exudation of organic acids, greater root growth along with modified root architecture, expanded root surface area by prolific development of root hairs, and enhanced expression of P_i transporters and aquaporins (1,8-11).

By far the most prevalent evolutionary adaptation by land plants for acquiring P_i (80% of all species) is through mycorrhizal symbioses.

PROTEOID ROOTS OF WHITE LUPIN

Significance

Proteoid roots (also known as cluster roots) are third order lateral roots that resemble bottle brushes in appearance.
They develop in response to low P in the Proteaceae, Fabaceae, Casuarinaceae, Betulaceae, Myricaceae, Eleagnaceae, and Moraceae.\[11\] Along with mycorrhizal association and nitrogen-fixing root nodules, proteoid roots are the third major adaptation by plants for acquisition of scarce nutrients. The well-characterized legume white lupin is an illuminating model for understanding proteoid root formation and plant adaptations to low P habitats.\[1,9–11\]

White lupin can effectively acquire P\(_i\) even though it does not form a mycorrhizal symbiosis.\[1,10,11\] Instead, its adaptation to P stress is a highly coordinated modification of root development and plant metabolism resulting in proteoid roots that exude copious amounts of organic acids and acid phosphatase.\[1,9,10\] Proteoid root formation is accompanied by extensive root hair formation that increases root surface area by greater than 100-fold. In addition, P\(_i\) uptake within proteoid root zones is much greater than that of normal roots. The developmental and metabolic changes that occur to give rise to proteoid roots are mediated in part by enhanced accumulation of transcripts encoding P\(_i\) transporters, exuded acid phosphatase, and enzymes of carbon metabolism.\[1,9,10\]

**Development**

Several features distinguish proteoid root development and morphology from that of typical dicot lateral roots. First, lateral roots are randomly initiated from the pericycle of primary roots near the zone of metaxylem differentiation,\[1,11\] whereas proteoid roots are initiated in waves along secondary roots (Fig. 1). Second, lateral roots are initiated singularly opposite a protoxylem point, in contrast to proteoid roots that are in multiples opposite every protoxylem point within the wave of differentiation. Third, in typical lateral roots, root hair development is highly regulated and occurs from a discrete number of epidermal cells. By comparison, in proteoid roots self-regulation of root hairs has gone awry with superabundant formation. Last, contrasting with the indeterminate growth of lateral roots, proteoid root growth is determinate, ceasing shortly after emergence (Fig. 1). This highly synchronous developmental pattern indicates that proteoid root formation is a finely tuned process. Moreover, because root pericycle cells are arrested in the G2 phase of the cell cycle,\[1,11\] proteoid root initiation must involve concerted release of multiple pericycle cells from the G2 phase in a wavelike pattern along second order lateral roots.

As might be expected, the internal balance and distribution of the plant growth hormones auxin, ethylene, and cytokinin are thought to play a role in proteoid root formation. Substantial support for the role of auxin in lateral root development is derived from evidence that: 1) exogenous auxin stimulates lateral root formation in most species; 2) auxin transport inhibitors block lateral root formation and this block can be alleviated by exogenous application of auxin; and 3) *Arabidopsis* mutants that overproduce auxin have enhanced lateral root formation, whereas mutants insensitive to auxin have impaired lateral root development. Gilbert et al.\[11\] have shown that exogenous application of auxin to P-sufficient white lupin mimics proteoid root formation seen under P-deficient conditions. They also showed that auxin transport inhibitors block the formation of proteoid roots on P-deficient

plants. Although the role of ethylene in lateral root formation is less clear, there is convincing evidence that ethylene plays a role in root hair formation and abundance. Consistent with the abundant root hairs found on P-deficient proteoid roots, Gilbert et al.\(^1\) found that ethylene production was increased twofold during the initiation and emergence of proteoid root initials of P-deficient plants compared to P-sufficient plants. Exogenous application of kinetin also inhibits proteoid root formation in P-stressed white lupin. Although we have not measured cytokinin content of P-stressed white lupin, it is revealing that an abundantly expressed EST in white lupin responsive to P-stress is cytokinin oxidase.\(^9\)

**Root Exudation of Organic Acids and Acid Phosphatase**

Although there is a large reservoir of inorganic and organic P in soil, most of it is unavailable because it is complexed to metals and/or organic residues.\(^{1,10,12}\) Exudation of organic acids and acid phosphatases from roots is a hallmark adaptation of plants growing in soils with low available P.\(^{10}\) The release of organic acids from roots allows for the displacement of P from Al\(^{3+}\), Fe\(^{3+}\), and Ca\(^{2+}\)-phosphates, thus freeing bound P.\(^{11,10}\) Organically bound P, which can compose as much as 70% of the soil P pool, can be hydrolyzed by acid phosphatases, thus freeing a large pool of unavailable P. These root adaptations to insufficient P are strikingly displayed by proteoid roots of P-deficient white lupin.

Proteoid roots of P-deficient white lupin synthesize and exude copious amounts of malate and citrate (Fig. 1). In the rhizosphere of white lupin grown in calcareous soil, the citrate concentration can be as high as 50 \(\mu\text{mol} \times g^{-1}\) soil\(^{-1}\). Between 10 and 25% of the total carbon fixed during P-stress can be released as malate or citrate. Radiolabeling studies show that nonautotrophic \(\text{CO}_2\) fixation in proteoid roots can provide up to 30% of the carbon exuded in citrate and malate. The increased synthesis of organic acids in P-deficient proteoid roots is mediated by highly enhanced activity of malate dehydrogenase (MDH), phosphoenolpyruvate carboxylase (PEPC), and citrate synthase (CS) with an accompanying decrease in aconitase (AC) and respiration rates. Recent molecular studies show that increased PEPC and MDH activities are due in part to enhanced expression of PEPC and MDH genes.

Accompanying the acidification of the rhizosphere of P-deficient white lupin proteoid roots is the excretion of large amounts of acid phosphatase (Fig. 1). Although the release of acid phosphatase and phytase is a common response of plant roots to Pi-stress, only in white lupin proteoid roots have the biochemical and molecular events involved yielded to experimentation. Under Pi-stress, proteoid roots synthesize and secrete a novel isoform of acid phosphatase (SAPase).\(^{11}\) Characterization of SAPase protein and cDNA from white lupin exudates revealed that the enzyme was synthesized as a 52 kD protein having a 31 amino acid presequence. The presequence targets the protein to outside the cell. Upon exudation, cleavage of the presequence results in a 49 kD processed protein. The formation of a novel SAPase results from increased SAPase mRNA and protein synthesis in proteoid roots (Fig. 2). The promoter region of the SAPase gene has
cis-acting element(s) that control P-stress-induced gene expression. Similar biochemical and molecular events appear to control P-starvation-induced acid phosphatases in suspension cell cultures of *Brassica nigra*.

**Phosphorus Uptake**

Inorganic orthophosphate (such as $\text{H}_2\text{PO}_4^-$ and $\text{HPO}_4^{2-}$) is the form of $\text{P}_i$ most generally taken up by plants.$^{[13,14]}$ After diffusion through the soil to the root surface, $\text{P}_i$ is rapidly taken up, resulting in a $\text{P}_i$ depletion shell of 0.2 to 1.0 mm around the root. Although the soil solution $\text{P}_i$ concentration rarely exceeds 2 $\mu$M, that in plant cells is much higher, 2 to 20 $\text{nM}$. For the plant to surmount this concentration difference, active (energized) transport across the plasmalemma is required. The striking reduction in $\text{P}_i$ accumulation of tissues treated with inhibitors reflects this energy requirement for uptake.$^{[12,13]}$ Moreover, kinetic analysis of $\text{P}_i$ uptake shows that plants have both a low- and high-affinity uptake system.$^{[10,12,14]}$ The high-affinity system operating at low $\text{P}_i$ concentrations has an apparent $K_m$ ranging from 3 to 10 $\mu$M. By comparison, the low-affinity system operating at high $\text{P}_i$ concentrations has a $K_m$ ranging from 50 to 300 $\mu$M. Recently, functional complementation of yeast mutants defective in $\text{P}_i$ transport has been used to isolate and characterize $\text{P}_i$ transporters from a diverse array of plants.$^{[13,14]}$ Molecular characterization of $\text{P}_i$ transporters coupled to the discovery of as many as 16 within the genome of *Arabidopsis* confirms that plants have a multiplicity of $\text{P}_i$ transporters functional in specific organs and tissues.

Uptake of $\text{P}_i$ by $\text{P}$-deficient proteoid roots is much greater than that of $\text{P}$-sufficient plants.$^{[10]}$ Moreover, the apparent $K_m$ for $\text{P}_i$ uptake of proteoid roots is 8.6 $\mu$M, compared to a $K_m$ of 30.7 $\mu$M for $\text{P}$-sufficient controls. These results suggest that a high-affinity $\text{P}_i$ uptake system is induced in proteoid roots of $\text{P}$-deficient plants. We have recently characterized a high-affinity type $\text{P}_i$ uptake gene (LaPT1) from proteoid roots of white lupin that shows highly intensified expression in $\text{P}$-deficient plants.$^{[1]}$
Similar to other plant Pi transporters, the white lupin proteoid root Pi transporter has a 1620 base pairs (bp) open reading frame that encodes a protein of 540 amino acids with a Mr of 59 kD. The deduced protein contains 12 transmembrane domains that occurs as two groups (6+6) connected by a hydrophobic domain of 60 amino acid residues (Fig. 3). The deduced amino acid sequence of LaPT1 is 85% similar to previously reported high-affinity type Pi transporters, but only 75% similar to low-affinity type Pi transporters. Transcripts of LaPT1 are highly expressed in Pi-deficient proteoid roots, normal roots, and stems with little to no expression in P-sufficient plants (Fig. 2). Thus, the enhanced uptake of Pi displayed by Pi-deficient proteoid roots can be directly related to increased expression of a high-affinity type Pi transporter.

CONCLUSION

Phosphorus has and will continue to play a major role in crop productivity because of its role in all phases of plant growth. However, the adverse impact that excess P has on water quality, coupled with depletion of cheap sources and lack of availability in the developing world, necessitate that plant scientists unravel the mechanisms leading to improved P acquisition. Proteoid roots of white lupin offer an excellent model for understanding P-acquisition strategies that both improve acquisition and conserve use of the critical nutrient. By discovering how plants control adaptation to low-P environments through changes in metabolism, development, and gene expression, we can begin to identify targets to improve P acquisition through conventional and biotechnological methods.

Photoacoustics: Listening to Plants

Shumel Malkin
The Weizmann Institute, Rehovot, Israel

INTRODUCTION

Photoacoustics (PA) is a methodology concerning the measurement of minute transient pressure changes resulting from light absorption.\textsuperscript{[1,2]} For good detection the light intensity must vary rapidly, so light is brought in as a single pulse or flash or is modulated periodically. Several variations exist in PA, depending on the state of the sample (i.e., gas, liquid, homogeneous or porous solid) and the time-scale and time-profile of the light. The pressure changes are sensed by a suitable detector (e.g., a microphone, a piezoelectric device, or a similar gadget), which generates a measurable electrical signal (the PA signal). PA is applicable for spectroscopy and analytical determination down to very low concentrations (to the parts per billion range).\textsuperscript{[1–6]} A significant application is the measurement of (gross) photosynthesis\textsuperscript{[5–11]} and its related parameters, including energetic and regulatory aspects. PA is particularly unique in leaf measurements, being a noninvasive, rapid, and sensitive technique.\textsuperscript{[8]} The interested reader may find wider coverage of the subject using the small representative bibliographic list. While this list is very limited, it may serve as a starting point for a more comprehensive search.

THE PHOTOTHERMAL MECHANISM AND SPECTROSCOPY—ANALYTICAL APPLICATIONS

A universal mechanism that produces pressure changes is the temperature rise caused by the absorption of light energy and its conversion to heat (photothermal mechanism).\textsuperscript{[11]} If this is the sole mechanism and if the conversion of light energy to thermal energy is complete, the PA signal, being related directly to the extent of light absorption, may be used for spectral analysis of the sample. PA spectroscopy\textsuperscript{[1–4]} is a direct method, in contrast to conventional spectroscopy, in which the intensity of a transmitted beam is compared to that of an incident beam. PA spectroscopy has a clear advantage in two extreme cases: 1) for almost fully transparent materials, when the difference between the intensities of the incident and transmitted beams cannot be accurately determined; and 2) for very opaque liquid or solid samples, in which conventional spectroscopy requires impractical very small optical lengths (usually in the order of micrometers). This problem is circumvented in PA. Solid and liquid samples can be analyzed by a conventional gas-coupled microphone PA cell, in which a microphone is placed in the gas (air) phase surrounding the sample. Light, modulated at some frequency (practically ca. 5–2000 Hz), is incident on the sample’s cross-sectional side, which is in contact with the gas phase. There is a heat flow, from the light absorption path through the sample, toward the gas phase. The light modulations cause modulations in heat generation, which diffuses to the gas phase, and, in turn, causes modulated pressure changes in the gas phase. However, the modulation in the heat flow is strongly damped along its diffusion path, in accordance with the heat conductance equation. Accordingly, light absorption in only a limited small depth below the surface (in the order of micrometers, depending on the modulation frequency) is expressed as a PA signal.\textsuperscript{[11]}

The PA signal, obviously, depends on the thermal conduction and heat capacity, and might be used for their measurement. For a nonhomogenous sample it is possible to scan the PA signal through the sample’s cross section at various frequencies and obtain information on the depth profile inhomogeneity of the thermal and optical parameters. These can be expressed by imaging.\textsuperscript{[1,2]} For illustrations of PA cells and systems see Figs. 12.1 to 12.6 in Ref. [1], Fig. 1a in Ref. [7] and Refs. [1,6] quoted in Ref. [7].

Gaseous materials are likewise analyzed in a gas-coupled microphone cell, where light is absorbed directly in the gas phase and pressure changes are developed momentarily therein. An example relevant to the plant sciences is the determination (down to sub parts per billion concentrations) of gases that are evolved from various metabolic processes in plants, fruits, and food stuff, e.g., ethylene, ammonia, methane, etc.\textsuperscript{[3,4]} Nitrogen fixation can also be monitored by the accompanying gas evolution. The PA cell is contained in a gas flow system, with a carrier gas passing through a sample chamber. A modulated infrared laser is passed through the flowing gas in a tube, after selecting a suitable wavelength absorbed by the analyzed gas in question. The PA signal is proportional to the concentration. Very suitable are CO
or \( \text{CO}_2 \) lasers, containing many wavelength lines, one of which at least is absorbed by the materials in question. For illustrations of the experimental system and details of the many applications, see Refs. [3,4]. (Notice that in Ref. [4] the legends to Figs. 3 and 5 were erroneously switched.)

Another example, relevant to water quality and primary production, is the determination of photosynthetic biomass in natural water.\(^6\) For this case, another version of a PA cell is used in which the pressure sensor (e.g., piezoelectric) is coupled to the analyzed water, either directly or through intervening solid or liquid materials and not through a gas phase. Usually, a laser pulse of a small cross section (relative to the cell dimension) is passed through the middle of the sample. It generates an acoustic wave pulse propagating from the light path through the suspension to the detector. A transient wave-form signal impulse is obtained, in the microsecond time range, which is a superposition of effects due to the various photochemical processes. This mode of PA\(^{2,5,6,10,13}\) may be called pulsed, time-resolved photoacoustics (PTRPA). An alternate name is laser-induced opto-acoustic spectroscopy (LIOAS).\(^2\) The PA-signal waveform depends on the light profile, the physical mechanisms that are expressed as pressure changes, and the physics of acoustic wave propagation. The PA signal in this case is a composite of the photothermal and another mechanism (cf. below). However, one may obtain conditions where only the photothermal mechanism is present. In any case the PA signal amplitude is proportional to the concentration of the photosynthetic pigments.\(^6\) There are accompanying methods that measure the photothermal effect alone, e.g., photothermal radiometry (PTR),\(^{1,2,7}\) based on the emission of modulated thermal radiation from the sample. This method was used only occasionally in photosynthesis.

**PA-SIGNAL FORM AND ATTRIBUTES**

The PA-signal form depends on the PA-cell arrangement and the light profile.\(^2\) For periodically modulated light the signal is characterized by its *amplitude* and *phase*, relative to the amplitude and phase of the exciting light. Mathematically, the modulated light intensity may be expressed by

\[
I = I_0 (1 + \sin(2\pi ft)),
\]

where \( I \) is the momentary light intensity, \( I_0 \) its amplitude, \( f \) the frequency, and \( t \) the time. The resulting PA signal is given as

\[
S = S_0 \sin(2\pi ft - \phi),
\]

with \( S_0 \) the amplitude and \( \phi \) the phase. Signal analysis is usually performed by a lock-in amplifier, yielding these signal attributes and their possible changes in a time scale longer than the period time. Light modulation is often produced by a chopper, resulting in a periodic train of square pulses. Still, the above formulae are valid, selecting the first term in a Fourier series decomposition of the signal.\(^{7,8}\) This measurement mode is called frequency-domain measurement (i.e., each single experiment is locked to one frequency and a frequency span is required for complete information). In a time-domain measurement mode, one uses a single (square) light pulse,\(^9\) or a short flash\(^{2,5,6,13}\) as described above. The pressure changes are measured vs. time, from their creation to their complete relaxation. Usually, signal averaging over several experiments is required.

**LISTENING TO PHOTOSYNTHESIS**

### Photothermal Mechanism and Energy Storage

Originally, the idea to use PA measurements in photosynthesis was to estimate how much of the absorbed light energy in photosynthetic pigments is stored as chemical energy and not converted to heat. A comparison between an active sample and a reference, which has the same light absorption and thermal properties and in which light energy is fully converted to heat, shows that the photothermal PA signal from the former is smaller than that from the second. The difference is a measure of energy storage.\(^{2,5,7,8,10}\) This concept was initially applied successfully for suspensions of photosynthetic membranes and microorganisms. The reference is routinely obtained by adding temporarily strong nonmodulated light (‘‘background light’’). In this case electron transport is oversaturated and most of the absorbed photons do not perform photosynthesis, ending solely in prompt heat production. For an illustration, see Fig. 1 in Ref. [10].

### Photobaric Mechanism—PA Signals Due to Photosynthetic Oxygen Evolution

PA measurements in plant leaves and lichens disclosed that photosynthetic oxygen evolution contributes also to PA-signal generation.\(^{5,7-11}\) This is because the input of a modulated stream of new gaseous material—the oxygen evolved by photosynthesis—into the restricted volume of a gas phase obviously results in modulated pressure changes. The PA signal from leaves is usually an independent superposition of the photothermal and oxygen evolution mechanisms, each with its own amplitude and phase. This is demonstrated in a frequency-domain PA experiment in a leaf, by alternately exposing the leaf to an additional background light, sufficiently strong to oversaturate
photosynthesis. Under the strong light, oxygen evolution becomes light-intensity independent and is not influenced by the modulated light. The oxygen evolution contribution to the PA signal is therefore eliminated by the background light, resulting in a significant decrease in the amplitude and a considerable phase change of the PA signal. A parallel PTR experiment, which monitors the photothermal effect alone, does not show this effect, confirming this interpretation. For an illustration, see Fig. 2 in Ref. [10].

A more direct demonstration is provided in a time-domain experiment showing the two PA-signal components separated in time as illustrated in Fig. 26.2 in Ref. [8] and Fig. 3 in Ref. [10]. The photothermal component rises first. The oxygen evolution component lags, still increasing after light termination before its final decrease. The last component is eliminated with strong background light, as above. At the same time the background light causes an increase in the initial slope of the photothermal part. By assuming that the (photothermal) initial slope is proportional to the extent of light energy conversion to heat, energy storage can be estimated. The slowness of the oxygen evolution signal component results from its slow diffusion in the intervening aqueous phase (see below).

The mechanism where gas evolution or uptake forms a PA signal is termed photobaric. Under special conditions photobaric signals due to gas uptake also occur in leaves. Many characteristics of the photobaric component confirm its assignment and locus of generation. At small frequencies (less than ca. 30 Hz), in frequency-domain measurements, it is often much stronger than that of the photothermal one, but it strongly decreases as frequency increases. At sufficiently high frequencies (greater than ca. 300 Hz) it is negligible compared to the photothermal component. Theory predicts indeed a frequency-dependent strong damping of the modulation in the oxygen evolution due to its diffusion in the aqueous phase toward the outer gas phase. From the measured dependence of the photobaric signal vs. frequency, an effective diffusion distance in the order of micrometers was found, consistent with PA-signal generation in the inner air phase. Indeed, the photobaric component is absent when the leaf is water infiltrated, because of the increase in the diffusion distance.

Parallel behavior of the assumed photobaric signal and photosynthetic oxygen evolution further confirms the above assignment. Examples are the brief oxygen evolution gush and the slow development of oxygen evolution (photosynthetic induction) following dark adaptation; the effect of inhibitors and environmental stress conditions; and the pattern of PA signals, in time-domain experiments, obtained with serial flash excitations, which reflects the S-states advance of oxygen evolution.

Photosynthetic CO₂ uptake is not modulated at the ordinary frequency range and does not contribute to a PA signal. The photobaric signal therefore reflects gross photosynthesis. For good signal-to-noise ratio, PA cells must have small volumes (a fraction of a milliliter) and be tightly closed. The gas composition is therefore not well controlled. Under these conditions photosynthesis is maintained by CO₂ supplied by respiration. Hence steady-state PA measurements are performed at a compensation point. Special PA cells may be constructed for a better control of the gas composition either by adding input and output valves, with short periods of gas streaming, during which PA measurement is stopped, or by using a gas permeable wall. Another option is the open PA cell, with a leaf forming one of the enclosure walls.

**Photobaric PA Signals Due to Gas Uptake**

Under special conditions, photobaric signals due to gas uptake (rather than evolution) were noticed. One example occurs at very high ambient CO₂ concentrations (e.g., up to 5%), using a PA cell equipped with valves and filled with CO₂-enriched air. A similar situation arises also in a closed PA cell after a long dark adaptation, due to CO₂ enrichment by respiration. A similar effect occurs also when only a part of the leaf is enclosed in the PA cell and the expanded parts of the leaf outside the cell are exposed to CO₂-enriched air. In all the above cases, the signal direction becomes opposite (i.e., negative) to the normal photothermal or oxygen evolution signal. (The sense of the signal, positive or negative, is directly seen in time-domain measurement. In frequency-domain measurements, it is defined only at sufficiently low frequency.) It was shown that this effect requires the presence of carbonic anhydrase. Consequently, it was concluded that it reflects CO₂ uptake by changes in its solubility, following the light-induced modulated pH changes in the stromal space. For illustrations, see Fig. 5 in Ref. [9] or Fig. 26.18 in Ref. [8].

A different type of gas-uptake photobaric signal occurs after dark adaptation, which does not depend on CO₂. In this case modulated far-red light (ca. 700–740 nm), absorbed mainly by photosystem I, was used to excite the PA signal. With such light alone there is only a small photobaric signal. However, a large negative signal appears when (low-intensity) background light, absorbed in both photosystems, was added. The negative signal grows gradually to a considerable amplitude but finally dies away. This effect lasts about a minute or two. From various pieces of evidence it was concluded that this
signal is due to a transient oxygen uptake in photosystem I (oxygen photoreduction). For an illustration, see Fig. 2 in Ref. [12].

PA Signals in Algal Thalli

Algal thalli, like leaves, are very suitable for PA measurements in air-coupled microphone cells. Algal thalli do not produce detectable photobaric signals, behaving like water infiltrated leaves, because of the long diffusion distance in the aqueous medium.

PA Signals in Suspensions of Photosynthetic Microorganisms, Organelles, and Membranes: Signals Due to Photochemically Induced Volume Changes

Suspensions are not ideal samples of investigation in air-coupled microphone cells.[7] The suspension must be impregnated into some flat porous solid support (e.g., filter paper). For a reasonable signal-to-noise ratio, very high concentrations must be used, which are inconvenient for sample manipulation. In most cases such suspensions produce only photothermal signals, with notable exceptions of half-dried cells.[7] More suitable for suspensions is to use a liquid-filled PA cell with a directly coupled sensor and short flash excitation (PTRPA—cf. above).[2,5,6,13] Obviously, in such a case no photobaric signal can be detected. The PA signal is then a composite of the photothermal signal with another contribution from a change of molecular volume (chroic mechanism), normally reflecting light-induced contraction, which results from the initial steps of electron transport.[5,7,10,13] For illustrations, see Fig. 6 in Ref. [10] and Fig. 3 in Ref. [13].

Separation of the photothermal and chroic signals is based on the thermal properties of the aqueous medium, which are strongly temperature-dependent.[5,10,13] The photothermal signal is proportional to the product of the derivative of the specific volume (volume per unit mass) vs. temperature and the reciprocal of the specific heat capacity. Therefore the photothermal effect disappears at the singular temperature of water (ca. 4°C; for buffer solutions the singular temperature may vary around this point), from which the chroic effect is isolated. Both the molecular volume change and energy storage can be deduced from plots of the PA signal vs. the above parameter, for the sample and a proper reference in which there is no molecular volume change and the conversion of light to thermal energy is complete. Such reference may be obtained by using a proper inert dye solution, using the same buffer and the same light absorbance, or by adding strong background light to the investigated sample.

Applications

Energy storage and molecular volume changes yield important information regarding the thermodynamic, electrostatic interactions and energetic aspects of photosynthesis,[5,7,8,10,13] in particular the initial electron-transfer steps.[13] Time-dependent energy transformations are obtainable, in principle, from energy-storage measurements vs. frequency.[5,7,8] Energy storage and the photobaric signal are markers of activity for monitoring plant productivity and condition in general.[7,8,10] Light saturation profiles, wavelength dependence, and transient phenomena, signifying regulatory processes, are readily obtainable. The responsiveness of the method to modulated light only allows an interplay of modulated and background light of different wavelengths to measure specific properties as a function of the wavelength, e.g., light distribution between the two photosystems in leaves, cyanobacteria and various marine algae and processes that change this distribution,[7,8] special wavelength dependence that gives a clue to monitor cyclic electron flow,[7,8] oxygen photoreduction (cf. “Photobaric Mechanism—PA Signals Due to Photosynthetic Oxygen Evolution’’); and CO$_2$ solubilization.[9,12] The feasibility of microscopic scale PA measurements in leaf tissues and depth profile analysis was recently reported.[10] The list of applications is probably not yet exhausted.

CONCLUSION

The photoacoustic method offers many advantages in analytical plant research and in particular in photosynthesis research. Plant products can be analyzed by the PA method with an unsurpassed detection limit. In photosynthesis, particularly leaf photosynthesis, PA serves as a unique noninvasive method, capable of several measurement modes. The basic one is that of monitoring the rate of the process as such (following pressure changes due to oxygen evolution). However, in addition it measures in real time various other variables of the photosynthetic apparatus (energetic parameters, relations between the two photosystems, adjustment to the environment, etc.). On the other hand, this rich repertoire is also a drawback, requiring careful examination and separation of the conditions that influence each of the parameters. Another drawback is the present unsatisfactory control of gas composition around the leaf, which calls for serious technical development for its solution. In spite of these
drawbacks, PA may be regarded as an indispensable method, bringing new insights to the research.

Photoperiodism and the Regulation of Flowering

Isabelle A. Carré
University of Warwick, Coventry, U.K.

INTRODUCTION

Responses to day-length, or photoperiod, enable plants and animals to adapt their physiology in anticipation of seasonal changes in climactic conditions. Many aspects of plant development are regulated by photoperiod, including seed germination, bud dormancy, stem and leaf growth, and formation of bulbs and tubers. The appropriate timing of reproductive activity is particularly important in order to maximize survival of the offspring. Flowering and seed production rely on suitable light and temperature conditions, but are also affected by the degree of competition with other species. In order to minimize such competition, different species have evolved a range of day-length responses that enable them to flower at different times of the year and occupy different ecological niches. For example, short-day plants flower in the spring or autumn when the total duration of light within a day is shorter than a critical photoperiod, whereas long-day plants flower in the summer when the photoperiod is longer.

The discovery of photoperiodism in the early 1920s has had a profound impact on agricultural and horticultural practices. Many commercial crops exhibit day-length responsive flowering, and the systematic testing of photoperiodic requirements can prevent failure of new varieties. The manipulation of day-length using black-outs or supplementary lighting allows flowering to be induced at any time of the year and enables breeders to obtain multiple generations per year. Commercial growers can grow potted ornamental plants out of season and precisely schedule their flowering for commercially important dates. Poinsettia, chrysanthemum, Christmas cactus, and begonias are examples of crops managed in this manner.

Recent studies of Arabidopsis (a long-day plant) and rice (a short-day plant) have identified genes that mediate floral responses to day-length. Emerging models for the photoperiodic sensing mechanism are described.

THE TIMING MECHANISM

Perception of photoperiod requires a biological timer measuring the duration of light and (or) darkness. This function is mediated by a 24-hour pacemaker known as the circadian clock. In Arabidopsis, the mutation or misexpression of any of the known components of this clock (including LHY, CCA1, TOC1, ELF3, GI, ZTL, LKP2, and FKF1) leads to abnormal floral responses to photoperiod.[1]

Two different mechanisms have been proposed by which a circadian clock might mediate perception of seasonal changes in day-length.[2] The effect of changes in photoperiod may be to bring two different rhythms to a more favorable phase-relationship (internal coincidence). Alternatively, responses may be triggered when light coincides with a sensitive phase of a photoperiodic response rhythm (external coincidence). The photoinducible phase may be determined by the temporal pattern of expression of a regulatory molecule, and rhythmic expression of the floral regulator CONSTANS (CO) has been proposed to play such a role in Arabidopsis.[3] In support of this model, atypical light-dark cycles that altered the

Fig. 1  Rhythmic expression of the CO transcript under short and long-day conditions. Similar patterns were observed in Arabidopsis and rice.[3,7] White and black boxes under the graphs represent intervals of light and darkness, respectively. Shaded areas under the curve indicate the levels of CO coincidence with light.
phase-relationship between the CO expression rhythm and the photoperiod also altered floral responses.\[4\]

**DOWNSTREAM OF THE CLOCK: ROLE OF CONSTANS AND OF ITS TARGET GENES**

In *Arabidopsis*, expression of the CO transcript is rhythmic.\[3\] Under 24-hour light-dark cycles, accumulation begins eight hours after dawn, and peak levels are reached after 16 hours. Thus, under noninductive short-day conditions, expression of CO is restricted to the dark interval, but the first half of the CO mRNA peak coincides with light under inductive long-day conditions (Fig. 1). The CO protein exhibits homology to transcription factors of the zinc finger family.\[5\] As it is highly unstable, its expression pattern is predicted to resemble that of the mRNA. Coincidence of CO expression with light may lead to its post-translational modification. The light-activated CO protein may become capable of activating transcription of its immediate target genes, FT and SOC1\[3,6\] and trigger conversion of vegetative meristems into floral meristems (Fig. 2).

Rice FT-like genes (*Hd3A, RFT1, FTL*) also function as positive effectors of flowering.\[7\] and the rice counterpart of CONSTANS (*SE1*)\[8\] is expressed rhythmically with a phase similar to that of CO in *Arabidopsis* (Fig. 1). However, SE1 inhibits expression of FT-like genes under long days and promotes it under short-day conditions.\[7\] Thus, the basic mechanism of day-length perception is conserved between rice and *Arabidopsis*, and the change of sign of the flowering response between short- and long-day plants may take place downstream of CO at the level of the regulation of FT transcription (Fig. 2).

**PERCEPTION OF LIGHT SIGNALS**

In the external coincidence model, light affects photoperiodic responses by two different mechanisms (Fig. 3). One effect of light is to mediate synchronization (entrainment) of the circadian clock to diurnal changes in...
environmental conditions (solid arrow). Light-dark transitions set the phase of the clock, and thus determine the time of the day when floral responses can be induced. In *Arabidopsis*, this effect of light on the circadian clock is mediated by a broad range of photoreceptors, including phytochromes A, B, D, E, as well as cryptochromes 1 and 2.\[9\] Another effect of light is to trigger the photoperiodic response when its presence coincides with the photoresponsive phase of the photoperiodic response rhythm (dotted arrow). The blue light photoreceptor cryptochrome 2 (CRY2) plays a major role in the perception of photoperiodic signals in *Arabidopsis*, and plants lacking CRY2 function do not exhibit FT induction under long-days.\[6\] In contrast, the red/far red photoreceptor phytochrome appears to mediate perception of daylength in rice. As in *cry2* mutants of *Arabidopsis*, loss of phytochrome (SE5) function in rice abolished responses to long days. The se5 mutant plants flowered as early under inhibitory long-days as wild-type under inductive short-day conditions.\[10\]

**CONCLUSIONS AND PERSPECTIVES**

Many aspects of the day-length response remain to be investigated. The mechanism by which light regulates CO activity is not known. There is evidence that diurnal changes in CRY2 protein levels are required for appropriate perception of day-length in *Arabidopsis*,\[11\] but the mechanism of these changes and their contribution to the photoperiodic response are not understood.

Comparison of patterns of CO and FT expression in a wider variety of plant species will determine whether rhythmic expression of these proteins may explain the range of day-length responses described in Table 1. The elucidation of photoperiodic timing mechanisms will enable the rational breeding and (or) engineering of crop varieties that are day-length insensitive. Alternatively it may be possible to alter the critical photoperiod for floral induction to allow growth of particular crops or ornamentals under latitudes that differ from their country of origin.

INTRODUCTION

Plants rely on information from their surrounding environment to synchronize development to daily and seasonal changes. Many of these adaptive changes are mediated in response to alterations in day length and light quality. In higher plants, the need to sense and interpret these environmental cues in a meaningful way has led to the evolution of highly sophisticated light signaling networks. Controlling these networks are families of photoreceptors whose collective action shapes growth and development via a process that is referred to as photomorphogenesis.

The phytochrome family of photoreceptors plays a pivotal role in this photosensory network controlling a diverse range of responses, from seed germination, de-etiolation, to cell elongation and flowering. In the model plant Arabidopsis thaliana there are five members of the phytochrome family: phyA, phyB, phyC, phyD, and phyE. These photoreceptors, which absorb mainly in the red (600–700 nm) and far-red (700–800 nm) regions of the electromagnetic spectrum, are able to monitor closely and respond to changes in the light environment. In recent years we have made significant inroads into defining roles for individual phytochromes; we have also begun to understand the nature of the signaling networks that they control.

ISOLATION AND CHARACTERIZATION OF PHYTOCHROME PHOTORECEPTOR MUTANTS

Analysis of mutants lacking one or more phytochromes has provided tremendous insights into the contribution of individual phytochromes and the interplay between phytochromes in the regulation of many developmental events. The phytochromes have an important role in de-etiolation and this was exploited to isolate the first phytochrome mutants. When grown in the dark Arabidopsis seedlings have elongated hypocotyls and small, folded, unexpanded, pale cotyledons. Exposure to the red, far-red, and blue components of white light triggers series of developmental changes that lead to de-etiolation: inhibition of hypocotyl elongation and opening, expansion, and greening of the cotyledons. Genetic screens designed to select for mutants that were deficient in de-etiolation under specific wavelengths of light led to the identification of the phyA and phyB null mutants. Several phyA mutants were isolated in screens for long hypocotyl mutants under far-red light.\(^1\) Indeed, phyA mutants were shown to be completely insensitive to far-red light and they resembled dark-grown seedlings when grown under these conditions. This demonstrated that wild type phyA was important for mediating responses to de-etiolation in FR light.

PhyA has different properties from the other phytochromes. It accumulates to high levels in imbibed seeds, and dark-grown seedlings. Upon exposure to light PfrA is rapidly degraded; thus, phyA is light labile.\(^2\) Careful physiological analysis of mutants null for phyA demonstrated that this phytochrome operates via two modes of action: the Very Low Fluence Response mode (VLFR) and the High Irradiance Response mode (HIR).\(^3\) VLFRs are saturated with very low fluences of light, whilst HIRs require longer periods of far-red irradiation at higher fluence rates. Extensive analysis of phyA mutants has shown that phyA is not just important for de-etiolation, but also has an extensive role in controlling development throughout the plant’s life. These roles include control of germination, photoperiod-dependent hypocotyl elongation, and the photoperiodic control of flowering.\(^1\)

Similar screens, but under white light, identified mutants that were null for phyB.\(^1\) Seedlings lacking phyB were shown to have a reduced sensitivity to red light and did not de-etiolate fully under those conditions. This indicated that phyB played a major role in controlling seedling de-etiolation under red light. In contrast to phyA, phyB does not degrade as rapidly when seedlings are exposed to light and so is more light stable. Indeed, phyB appears to be the most abundant of the phytochromes in light-grown seedlings.\(^5\) Responses demonstrated to be reversible by far-red light in the wild type were shown to be impaired in the phyB mutant.\(^1\) These experiments showed that red/far-red reversibility, the hallmark of phytochrome action, is a characteristic of phyB and other light stable phytochromes. This type of response is referred to as a Low Fluence Response or LFR. It is this property of phytochrome that enables the plant to monitor the proportion of red:far-red ratio accurately, a means of detecting neighboring plants and potential competition.
Such changes in light quality result from selective absorption by green vegetation, which enhances the proportion of far-red wavelengths in the reflected/scattered light. The consequent alteration in red:far-red ratio triggers a striking series of responses that include increased stem and petiole elongation and the acceleration of the transition to flowering. These responses, collectively known as the Shade Avoidance Response, appear to be an important survival strategy under unfavorable shade conditions. Mutants deficient in phyB strongly resemble wild type plants that have been exposed to low red:far-red ratio light suggesting a major role for phyB in this important suite of responses (Fig. 1).

The phyD mutation was discovered as a naturally occurring mutation in the Arabidopsis Wassilewskija accession. The phyE mutation was isolated in a genetic screen of mutagenised phyA phyB mutants that displayed a constitutively early flowering and elongated internode phenotype. The phyD mutant displayed a similar, but less marked seedling phenotype to phyB when grown under red light, suggesting a role for phyD in the control of de- etiolation. For many responses, when grown under standard laboratory conditions, the phyD and phyE monogenetic mutants were similar to the wild type. However, analysis of mutants lacking phyD or phyE in addition to phyB revealed overlapping roles for these phytochromes with phyB. It has been demonstrated that the relative contributions of individual phytochromes varies according to the response. Indeed, the hierarchy of photoreceptor action appears to be modified by developmental or environmental changes. For example, under short photoperiods, phyB and phyE appear to have prominent roles in the inhibition of flowering. We have recently shown that the phyB mutant–early flowering phenotype is temperature sensitive: flowering time, measured as rosette leaf number at bolting, in wild type plants and phyB mutants grown in 8 hour photoperiods at 22°C or 16°C. Bars represent the SE.

Fig. 2 The phyB mutant flowering phenotype is temperature sensitive: flowering time, measured as rosette leaf number at bolting, in wild type plants and phyB mutants grown in 8 hour photoperiods at 22°C or 16°C. Bars represent the SE.

The picture that is emerging from several elegant genetic studies is one where the phytochromes act not in isolation, but as an integrated network. This network extends beyond the phytochrome family to other photoreceptors: the cryptochromes and phototropins. Indeed, cross-talk between these different photoreceptor pathways is well documented. Such an interconnected network has two main functions: It ensures transitional developmental response and it provides a buffer for environmental (e.g., changes in ambient temperature) and genetic variation in the maintenance of the response.

PHYTOCHROMES ARE COMPLEX LIGHT-REGULATED CHROMOPROTEINS

Phytochrome was first purified from etiolated oat seedlings by Butler and coworkers over forty years ago. In the intervening period we have discovered much about the properties of this molecule. Phytochromes exist as soluble dimers that comprise two polypeptides of approximately 125 kDa. The phytochromes are unique among the
Photoreceptors: They are photoreversible switches. Light induces interconversion between a red light-absorbing Pr form and a far-red light–absorbing Pfr form.[9–11] These distinctive spectral properties are conferred by phytochromobolin, a linear tetapyrrole chromophore that is covalently attached to the phytochrome apoprotein.[9–11] Each phytochrome monomer can be subdivided into an amino-terminal sensor and a C-terminal output domain.[9] It is the sensor domain that houses the chromophore, attached via the bilin lyase domain, also recognized as a GAF domain. Phytochrome GAF domains appear to belong to the bilin–lyase–specific subfamily of these ligand-binding domains. The regulatory or output region comprises two PAS-related domains (PRD) and a histidine-kinase–related domain (HKRD). PAS domains commonly bind small ligands and mediate protein–protein interactions. Similarities in the tertiary structure of PAS and GAF domains suggest there may be an evolutionary link between these two domains.[7,10] The HKRD, which is similar to histidine kinase regions found in bacterial two-component sensor proteins, together with the PRDs, provide a means via which the phytochrome dimer can transduce its signals. Indeed, work from several laboratories has provided strong evidence that support this notion.[7,11]

PHYTOCHROME SIGNAL TRANSDUCTION

In *Arabidopsis* seedlings light induces the radical change in gene expression required for the switch to skotomorphogenic to photomorphogenic development.[1,7] This developmental switch is triggered largely by phytochrome and cryptochrome action. Following photoactivation the phytochromes translocate from the cytoplasm to the nucleus where they cluster in nuclear speckles, the putative site of action.[3]

Defining the many phytochrome-controlled pathways is no small task. However, genetic screens and molecular techniques that detect protein–protein interactions have significantly enhanced our understanding of phytochrome signal transduction.[1,7] These studies have identified multiple phytochrome signaling intermediates and revealed that the phytochromes interact directly with several of these components. One such interaction partner is PIF3, a basic helix-loop-helix class of transcription factor, which preferentially binds to phyB in its active form (Pfr).[7] PIF3 also binds to the G-box DNA sequence motif common in the promoters of light-regulated genes. CCA1 and LHY, G-box containing genes and central components of the *Arabidopsis* circadian clock, were shown to be regulated by PIF3.[7] The circadian clock regulates many cellular processes and developmental responses; therefore, PIF3 may represent one mechanism via which light can interact to control these events.

Phytochromes display light-dependent Ser/Thr protein kinase activity.[11] This provides a possible mechanism via which phytochrome signals can be transduced in response to light signals. NDPK2, cry1, cry2, and PKS1 have been shown to interact with phyA and/or phyB. Furthermore, in vitro kinase assays, coupled with red light–mediated in vivo phosphorylation assays (for NDPK2, cry1, and PKS1) indicate that these proteins may be targets for phytochrome kinase activity.[7,11] The precise roles of NDPK2 and PKS1 in phytochrome signaling are not yet known. In contrast, physiological interactions between the cryptochromes and the phytochromes are well documented. It is, therefore, possible that some of these interactions result from modification of cryptochrome action via phytochrome-mediated phosphorylation.

CONCLUSION

Light cues that signal changes in the seasons or the immediate environment strongly influence growth strategy and the timing of development. The phytochromes detect these changes and act as an integrated signaling network to keep development in tune with the environment. Throughout development, it is equally important that responses are maintained under variable conditions. Indeed, the roles for individual photoreceptors and their hierarchy of action vary with developmental stage and environmental conditions.[4–6] This flexibility in the signaling network means that environmental change can be accommodated. Although great strides have been made in recent years we are still at an early stage in our understanding of phytochrome signaling. A major challenge for the future is to understand how the light signaling network is integrated. A multidisciplinary approach, combining molecular genetics, biochemistry, bioinformatics, and mathematical modeling, is required if we are to achieve this goal.

INTRODUCTION

Blue light affects many aspects of plant growth and development. The blue light responses of plants can be roughly divided into two large categories: photomovement responses and photomorphogenetic responses. Photomovement responses, including phototropic curvature, chloroplast relocation, and stomata opening, are mediated by phototropins. Plant photomorphogenetic responses, including inhibition of hypocotyl elongation, stimulation of cotyledon expansion, regulation of flowering time, entrainment of the circadian clock, and regulation of gene expression, are controlled by both phytochromes (in response to red/far-red light) and cryptochromes (in response to blue/UV-A light).

CRYPTOCHROME GENES AND PROTEINS

The term cryptochrome was coined in the late 1970s as a laboratory nickname for blue/UV-A light receptors that mediate plant blue light responses with the specific action spectra of a peak in the UV-A region (approximately 350–400 nm) and a peak with fine structures in the blue region (approximately 400–500 nm). The compound word is composed of -chrome for “pigment” (from the Greek chroma meaning color or pigment) and crypto- as in “cryptic” or “cryptogam.” This term was chosen because the molecular nature of blue light receptors remained hidden (cryptic) at the time in spite of extensive researches, and because the blue light responses are prevalent in cryptogams (plants without true flowers and seeds, such as ferns, mosses, algae, and fungi).[1]

Cryptochrome now refers to proteins that share sequence similarity to DNA photolyase but lack the photolyase activity. The first cryptochrome gene was isolated from Arabidopsis thaliana, which is a small weed widely used in laboratories because of its easy handling and small genome. In 1980, a number of Arabidopsis photomorphogenesis mutants were reported, one of which, called hy4, showed long hypocotyls when grown in blue light.[2] The gene corresponding to the hy4 mutation was isolated about a decade later, and it was found to encode a protein of 681 amino acids, for which the N-terminal sequence of approximately 500 amino acids was 30% identical to that of E. coli DNA photolyase.[3] DNA photolyases catalyze the blue/UV-A light-dependent cleavage of cyclobutane pyrimidine dimers that is a major type of DNA damage caused by short-wavelength (<300 nm) UV light.[4] To investigate whether the HY4 gene indeed encoded a blue light receptor, a full-length recombinant HY4 gene was expressed in insect cells and the recombinant protein purified.[5] The recombinant HY4 gene product is a yellow-colored soluble protein that bound noncovalently to flavin adenine dinucleotide (FAD). Cryptochromes may also contain a pterin as the second chromophore.[4] The facts that the HY4 gene product mediates a blue light response, shares sequence similarity to a blue light-dependent enzyme, and contains FAD, which absorbs both blue light and UV-A light, as a prosthetic group, indicated that it is a blue light receptor. The HY4 gene was renamed CRY1 (for cryptochrome 1) in 1995.[5]

Cryptochromes have been found throughout the plant kingdom, including among the angiosperms, ferns, mosses, and algae, and in animals including fishes, frogs, flies, mice, and humans.[1,4,6] Most plant species studied contain multiple members of the photolyase/cryptochrome gene family. For example, Arabidopsis has two cryptochrome genes, CRY1 and CRY2, and two photolyase genes; tomato and barley each have at least 3 cryptochrome genes, CRY1a and CRY1b, and CRY2; ferns and mosses have five and at least two cryptochrome genes, respectively.[1] The amino acid sequences of tomato CRY1 (CRY1a or CRY1b) and CRY2 are more similar to their Arabidopsis counterparts than to each other, indicating that the gene duplication event resulting in CRY1 and CRY2 occurred more than 100 million years ago at least, before the divergence of Brassicaceae (e.g., Arabidopsis) and Solanaceae (e.g., tomato).

Most plant cryptochromes have two domains, an N-terminal domain called PHR (for photolyase-related) that shares sequence homology with DNA photolyase, and a C-terminal domain called CCT (for cryptochrome C-
CRYPTOCHROMES MEDIATE VARIOUS PHOTOMORPHOGENETIC RESPONSES

Photomorphogenetic responses mediated by cryptochromes include blue light inhibition of stem elongation (Fig. 2), stimulation of leaf expansion, control of photoperiodic flowering, entrainment of the circadian clock, and regulation of gene expression. The functions of cryptochromes are conserved in different plants. It has been demonstrated that cryptochromes regulate hypocotyl inhibition in Arabidopsis and tomato. Different cryptochromes in the same plant can regulate the same light response. For example, in addition to CRY1, Arabidopsis CRY2 also contributes to the blue light inhibition of hypocotyl elongation response; and moss (Physcomitrella patens) CRY1a and CRY1b are both required for the blue light induction of side-branching on protonema. Different cryptochromes can also regulate distinct light responses. For instance, Arabidopsis CRY1 plays a more important role in hypocotyl inhibition, whereas Arabidopsis CRY2 plays a more important role in flowering-time control.

Although phytochromes are known to regulate photoperiodic flowering, it is now clear that cryptochromes also play significant roles in this response. The Arabidopsis laboratory strains Columbia (Col) and Landsberg erecta (Ler), both collected in the Northern Hemisphere, are nonobligate long-day plants that flower earlier in long days than in short days. The cry2 mutants isolated from these strains flower later than the wild type in long days but not in short days, so these cry2 mutants are late-flowering but more or less day-neutral. Another Arabidopsis ecotype, Cvi, collected from the tropical Cape Verde Islands, flowers earlier than many other Arabidopsis strains, and Cvi plants flower at about the same time in long days or in short days. The major QTL (quantitative trait locus) responsible for the day-neutral early flowering of the Cvi strain was determined to be the CRY2 gene. A valine to methionine substitution (V367M) in the CRY2 protein of the Cvi strain was found to be responsible for its day-neutral early-flowering phenotype. A cryptochrome can act as a day-length sensor by changing its relative abundance in response to photoperiods. The abundance of Arabidopsis cry2 protein shows a day-length-dependent diurnal rhythm. In short-day photoperiods, the level of CRY2 is lower in the day but higher in the night. In long-day photoperiods, such a diurnal rhythm of the CRY2 abundance is significantly diminished.
Cryptochrome is a major photoreceptor regulating the circadian clock in both plants and animals. In animals, cryptochromes act redundantly with rhodopsins to regulate the circadian clock. In plants, the entrainment of the circadian clock is controlled by both phytochromes and cryptochromes. Although it has been shown that cryptochrome is a photoreceptor for the entrainment of the circadian clock in the fruit fly, whether cryptochromes also provide light entrainment to the circadian clock in mammals such as humans or mice is still being debated. Plant cryptochromes act mainly as photoreceptors rather than as critical components of the circadian clock; in contrast, mammalian cryptochromes are critical components of the central oscillator.

CRYPTOCHROME SIGNAL TRANSDUCTION

The initial photoreaction of cryptochrome remains unclear. Because electron transport is involved in the photolyase-catalyzed DNA repairing reaction, a redox reaction has been proposed to be likely involved in the cryptochrome photochemistry. It is also not clear what the signal transduction mechanism is underlying cryptochrome regulation of photomorphogenetic responses. It has been proposed that cryptochromes may act to change ion homeostasis in the cell, or that cryptochromes, which are often found in the nucleus, may regulate gene expression to alter developmental processes. And at least two types of biochemical reactions have been demonstrated in the cryptochrome function: protein–protein interactions and a blue light-induced cryptochrome phosphorylation. Arabidopsis cryptochromes can interact with different proteins, including phytochrome B, COP1 (a putative subunit of E3 ubiquitin ligase complex known to be important for light-regulation of gene expression and hypocotyl inhibition), and ZTL (a PAS-domain-containing protein known to be important for the circadian clock and photoperiodic flowering). The functional significance of cry-COP1 interaction is demonstrated by the constitutive photomorphogenetic phenotype of Arabidopsis transgenic plants overexpressing CCT domain fusion proteins. The cry-phyB interaction may provide an explanation of why cry2 function is dependent on phyB. Arabidopsis cryptochromes have also been found to undergo a blue light-dependent phosphorylation, and the blue light-induced phosphorylation of Arabidopsis cry2 is important for its function and degradation. It has been proposed that cryptochromes are unphosphorylated and inactive in dark; blue light induces phosphorylation of cryptochromes by an unknown protein kinase; the phosphorylated cryptochrome becomes active in triggering photomorphogenetic responses; and phosphorylation-induced cryptochrome degradation is a mechanism to desensitize the photoreceptor.

CONCLUSION

Cryptochromes are blue/UV-A light receptors regulating various photomorphogenetic responses of plants, but the detailed molecular mechanisms of signal transduction of cryptochromes is not clear at present. Investigation of the interaction among signaling processes of cryptochromes, phytochromes, and phytohormones will also be critical to our understanding of how plants regulate their developmental processes in response to light.

INTRODUCTION

Plants have evolved a number of photoreceptor systems that mediate responses to a broad range of wavelengths from ultraviolet to near infrared. Several light-induced processes are specific to the blue (390–500 nm) and ultraviolet-A (320–390 nm) regions of the electromagnetic spectrum, including phototropism, regulation of stomatal aperture, and chloroplast position within mesophyll cells. Phototropism is the bending of a plant organ toward or away from a directional light stimulus. The phototropic response results from increased elongation of cells along one portion of the responding organ relative to cells in an opposing position. Stomata—small pores found along the surfaces of leaves and stems—are created between two guard cells fixed in position relative to each other at opposing ends. Because guard cells can swell or shrink in response to a variety of environmental signals (including light), stomatal pore size can change, allowing control of gas exchange and water release in leaves and stems. Mesophyll chloroplasts have the capacity to move within the cell to either maximize or minimize light capture. Although it has been known for some time that each of these responses is controlled by blue light, molecular studies have only recently identified the responsible blue-light photoreceptors, the phototropins.

ISOLATION AND CHARACTERIZATION OF THE PHOTOTROPIN 1 (PHOT1) MUTANTS

Two genes encoding proteins now classified as phototropins are found in the Arabidopsis genome. The first, PHOTOTROPIN 1 (PHOT1) (formerly called NPH1, for NON-PHOTOTROPIC HYPOCHOTYL 1), was not identified by genome sequencing but by classical genetics in a screen for Arabidopsis seedlings that failed to exhibit a hypocotyl phototropic response to low-intensity blue light. Not only are phot1 mutants impaired in their positive hypocotyl phototropism (bending toward light), but also in their negative root phototropism (bending away from light) in low-light intensities. In high-intensity light, phot1 mutants remained nonresponsive in the root, but recovered phototropism in the hypocotyl, indicating the presence of a second blue-light photoreceptor acting at higher fluence rates.

ISOLATION AND CHARACTERIZATION OF PHOT2 MUTANTS

A second likely phototropin gene, PHOT2 (originally designated NPL1, for NPH1-like1), was identified by genome sequence analysis by virtue of its 58% DNA sequence identity to PHOT1. A T-DNA insertion loss-of-function phot2 mutant was subsequently shown to have normal phototropic responses under both low- and high-light conditions when a phot1 phot2 double mutant exhibited essentially no phototropism under either light condition. Thus it appears that phot1 is required for phototropism under low light, whereas phot1 and phot2 play redundant roles in high-fluence rates (Fig. 1).

Mutant analyses have also associated phototropins with blue-light–induced chloroplast movements. In low-fluence blue light, mesophyll chloroplasts align along the periclinal walls of cells to maximize light exposure (accumulation response). In contrast, high light causes chloroplasts to relocate to the anticlinal walls in order to minimize light capture and thus avoid photodamage (avoidance response). Kagawa and colleagues identified phot2 mutants (initially designated as cav1, for chloroplast avoidance 1) in a screen for plants that failed to exhibit the chloroplast avoidance response. A similar lack of chloroplast avoidance response was found in reverse genetic analyses of phot2 T-DNA mutants. The singular role of phot2 in this high-light response differs from that observed with phototropism, where both phot1 and phot2 are responsible for photoperception in high light (Fig. 1). However, it appears that both phot1 and phot2 can signal the chloroplast accumulation response. Interestingly, the control of stomatal aperture also requires the activities of phot1 and phot2, but in yet another way. Unlike phototropism (in which the two photoreceptors signal the same response but at two different fluence rates) and unlike chloroplast movement (in which the two photoreceptors trigger two different responses), stomatal opening requires both phot1 and phot2 at all light intensities (Fig. 1).
PHOTOTROPIN PROTEINS ARE FLAVIN-BINDING LIGHT-ACTIVATED SERINE/THREONINE PROTEIN KINASES

A decade ago, Reymond and associates reported light-induced phosphorylation of a approximately 120-kilo-delta(kDa) membrane-associated protein with the phototropic response, and early work with the phot1 mutants demonstrated that they lacked this light-induced phosphorylation response. When PHOT1 was cloned by positional cloning it was found to encode a 120 kDa protein with a carboxyl-terminal serine/threonine kinase domain, making it likely that the phosphorylation response was in fact an autophosphorylation response. When PHOT1 was cloned by positional cloning it was found to encode a 120 kDa protein with a carboxyl-terminal serine/threonine kinase domain, making it likely that the phosphorylation response was in fact an autophosphorylation response. Christie and colleagues found that phot1 expressed heterologously in insect cells was autophosphorylated in response to blue light, indicating that all components necessary for the light-induced autophosphorylation—photoreceptor, kinase, and substrate—are present in phot1 itself.

The PHOT1 gene also includes two similar amino-terminal domains with 43% sequence identity to each other and similarity to a class of domains found in signaling proteins of various species. These domains are a subset of the PER-ARNT-SIM (PAS) domain superfamily, known to mediate protein-protein interactions and cofactor binding. Because proteins containing this subclass of PAS domains are responsive to light, oxygen, or voltage, these domains have been designated LOV1 and LOV2. In work by Christie and colleagues it has been found that the blue-light sensitivity described above is dependent upon binding of one flavin mononucleotide (FMN) molecule to each LOV domain, providing support for the hypothesis that a dual-chromophoric flavoprotein photoreceptor regulates phototropism in low-fluence blue light. Phot2, like phot1, is autophosphorylated in response to blue light and each of its LOV domains binds one FMN molecule.

A number of studies have examined the photochemical and photophysical properties of the LOV domains for phototropin proteins. Both optical and NMR spectroscopy have been used to demonstrate that phot1 LOV domains in solution undergo a dark-reversible photocycle that involves the formation of a C(4a) cysteinyl adduct between the FMN and the phot1 polypeptide. The formation of this adduct is consistent with the light-induced autophosphorylation of phot1. The FMN from either domain can be specifically labeled by the addition of a fluorescent FMN analog, providing a means to track the movement of the flavin in response to light. The effects of fluence rate on wild type, phot1 mutants, phot2 mutants, and phot1/phot2 double mutants with respect to (A) phototropism in the hypocotyl and root; (B) chloroplast movement; and (C) stomatal opening. 

**Fig. 1** The effect of fluence rate on wild type, phot1 mutants, phot2 mutants, and phot1/phot2 double mutants with respect to (A) phototropism in the hypocotyl and root; (B) chloroplast movement; and (C) stomatal opening. (View this art in color at www.dekker.com.)
of the reversible covalent linkage between phot1 LOV domains and the FMN chromophore has been confirmed by X-ray crystallography at a 2.6 Å resolution. The structural changes associated with this light-driven molecular switch presumably lead to activation of the carboxyl-terminal protein kinase domain.

PHOTOTROPINS FROM SPECIES OTHER THAN ARABIDOPSIS

Phototropins have been identified in several plant species besides Arabidopsis, including oat (Avena sativa), pea (Pisum sativum; accession number U83281), rice (Oryza sativa), and maize (Zea mays; accession number AF033263). Phototropins are not limited to higher plants, as a phototropin has also been found in the unicellular alga Chlamydomonas reinhardtii as well as the nonphotosynthetic bacterium Bacillus subtillis. The finding that apparent phototropins (based on similar sequence and predicted structure) exist in diverse taxa from prokaryotes to photosynthetic eukaryotes begs the question: Can we classify these proteins as either phot1 or phot2 and thus predict functions? The simple answer at present is maybe.

The PHOT genes in the various taxa can be classified as either PHOT1 or PHOT2 based on their sequence similarities to the Arabidopsis sequences. Moreover, in higher plants the phototropins can be classed as phot1 or phot2 based on mRNA expression patterns. For example, PHOT1 and PHOT2 also have very different gene expression patterns, with PHOT2 induced by blue light and PHOT1 gene expression reduced by blue light. These expression pattern differences fit nicely with the observed differences in physiological functions of phot1 and phot2 mutants in Arabidopsis under different light conditions. Kasahara and colleagues have recently suggested that phototropins can also be classified as either phot1 or phot2 based on discrete photochemical properties of the LOV domains in each, such as differences between LOV photoproduct formation and dark recovery. How the biochemical differences between the phototropin proteins relate back to differences in gene sequence has not yet been determined. Time will tell whether these generalizations hold true as more functional studies are done.

SIGNALLING DOWNSTREAM OF PHOTOTROPINS

Other nonphototropic hypocotyl (nph) mutants were isolated in the same screen that identified phot1. One of these, nph3, was phenotypically similar to phot1, suggesting that NPH3 function occurs early in the phototropism signaling pathway, possibly close to photoperception. Whereas there are no transmembrane domains in the NPH3 protein, it localizes to the plasma membrane. Like phot1, Motchoulski and Liscombe reported a physical interaction between phot1 and NPH3 by both a yeast two-hybrid and in vitro pull-down assays. NPH3 may function as a scaffolding protein to bring the photoreceptor, phot1, in contact with other downstream phototropism signaling components. The NPH3 homologue, RPT2 (for ROOT PHOTOTROPISM 2), may perform a similar function with phot2 under high light conditions. It is tempting to speculate that other members of the NPH3/RPT2 family may scaffold early signaling components for other physiological response that the phototropins regulate, such as chloroplast relocalization and stomatal control.

Electrophysiological studies are also providing additional insight for signaling events that occur downstream of phototropin activation. First, Baum and associates reported that high-intensity blue light causes transient increase in cytoplasmic Ca2+ within 20 seconds of the “lights on” signal. When phot1 mutants were exposed to blue light, the Ca2+ increase did not occur, suggesting that phot1 is the photoreceptor responsible for the increase in cytosolic Ca2+. Furthermore, they demonstrated that blue-light activation of the plasma membrane H+-ATPase does not occur in phot1 phot2 double mutants, providing a potential connection between the observed Ca2+ transients and responses controlled by phototropins.

CONCLUSION

Therefore, phototropins are involved in the regulation of multicellular (phototropism), cellular (stomatal opening), and even subcellular (chloroplast movement) responses in a semiredundant fashion. Each of these responses uses a unique combination of the two phototropins to respond to low-and high-intensity light. Clearly one of the challenges for the next decade is to identify downstream elements of phototropin-signaling pathways in both plant and non-plant species.

INTRODUCTION

Interest in the perception of ultraviolet began many years ago with physiological evidence for a putative UV-A/blue photoreceptor. As techniques have improved various receptors can be demonstrated to be operating in this region of the electromagnetic spectrum. In this article we examine what is known of these receptors, their response pathways and the interaction of these pathways.

THE RECEPTORS

It is now known that plants contain at least ten photoreceptors. These are five phytochromes (phy A–E), two cryptochromes, two phototropins, and a photoreceptor with properties akin to both phytochrome and phototropin and dubbed superchrome.

The major developmental photoreceptors, cryptochrome and phytochrome are capable of absorbing radiation in the UV part of the spectrum. The UV absorption spectra of Pfr and Pr are very similar and only small changes in Pfr/Ptot can be achieved. No ecological or physiological function has been ascribed to these changes. There is no evidence to date to indicate that the five species of phytochrome differ in their UV absorption although differences have been demonstrated in the visible part of the spectrum.

In recent years it has been revealed that there are two types of cryptochrome, CRY1, which can be stimulated by blue and UV-A radiation, and CRY2, which is stimulated by blue. The presence of this UV-A/blue receptor does not preclude the existence of other specific UV-A receptors that act independently, in association with each other, or in association with known photoreceptors.

Phototropins mediate phototropic responses with blue light, green light, and UV-A radiation. Identification has occurred in a number of species and is reviewed by Briggs et al.[1] Phototropins are proteins that have two LOV domains in the N-terminal region, which binds FNM as a chromophore.

UV-B radiation causes damage to DNA but there is also a good deal of evidence that indicates plants possess receptors to UV-B that cause developmental changes. The UV-B receptor has not yet been isolated and little is known of its signaling pathway. Evidence from current research could be assembled to suggest that a major function of UV receptors is to damp down the perception of the signal by the production of UV-absorbing metabolites. This could be of particular importance in reducing UV-B induced DNA damage. Much of what we know about UV-A and UV-B signaling has come from recent studies of UV-regulated gene expression in Arabidopsis. What is known[5–8] of the UV induction of chalcone synthase (CHS) in Arabidopsis is shown in Fig. 1. CHS appears to be controlled by a number of different photoreceptors and radiation conditions. Experimental evidence has suggested that CRY2 is regulated in the blue while CRY1 is regulated in the UV-A/blue. Using single and double phyA and phyB mutants, this group[4] is able to show that phytochrome is a positive regulator of the CRY1 inductive pathway with no preference for phyA or phyB and that there is interaction between CRY1 and phyB. UV-B can also control CHS. When this is so, neither CRY1 or CRY2 appear to be involved, nor is the synergy between blue and UV-A pathways involved with the UV-B response. PhyB is a negative regulator of the UV-B inductive pathway and since phyB acts upstream on the UV-B pathway from the points of synergism with blue and UV-A, it has been proposed that the flux through the UV-B and CRY1 pathways might be controlled by phyB.

UV-A RECEPTION

The study of the putative blue/UV-A has lead to our present understanding of the cryptochrome and these photoreceptors are dealt with elsewhere in this volume. However, any understanding of the integration of the signals received by the plant from the electromagnetic spectrum must take into account that in the presence of UV-A, CRY1 can be stimulated and cause developmental...
responses. The dual action maxima of CRY1 invites the question “Do plants have specific UV-A receptors?” A certain amount of evidence suggests that this may be so.

In an ecological study of a number of meadow species,[5] various growth parameters responded to elevated UV-A under outdoor conditions. These responses were further investigated with action spectra that were produced by growing *Cynosurus cristatus*, a common meadow grass, under polychromatic sources of UV, each with a different $\lambda_{\text{central}}$. In the action spectrum shown (Fig. 2), there is a sharp peak on the UV-B/UV-A border and a broad maximum throughout the UV-A. Under outdoor conditions, absorption of blue radiation by cryptochrome would be close to saturation and it is difficult to see, in terms of reciprocity, how the addition of so little energy could cause such significant responses unless UV-A was being received by a specific receptor with its own transduction pathway. Further, in a review of the growth responses of various *Arabidopsis* ecotypes to UV-A and UV-B+A, numerous responses were found to UV-A.[6] One ecotype in particular, Aa-0, was more sensitive to UV-A than UV-B.

**UV-B RECEPTORS**

UV-B radiation beyond the tolerance of a species will result in damage primarily due to the absorption of UV-B quanta by DNA resulting in dimerization. A secondary cause is the production of reactive oxygen species (ROS), which subsequently cause damage to DNA. However, besides damage, a pivotal role has been suggested for ROS (see below).

Responses to UV-B that are nondamaging or beneficial to the plant may include de-etiolation, flavonoid biosynthesis, leaf and hypocotyl development, regulation of leaf number, and branching frequency.[7] Evidence that these and other plant responses are under the control of a specific UV-B receptor come from a number of action spectra that have an action maximum between 290 and 300 nm.

Fine profile definition of the receptor cannot be expected at these wavelengths since a large number of...
molecules present in the plant tissues exhibit large changes in absorption and scattering in the UV region and can distort the shape of the action spectra. However, the unassailable argument is that if any of these responses were directly or indirectly linked to DNA damage, then wavelength efficiency would continue to rise with decreasing wavelength rather than form a maximum. Although phytochrome and flavins absorb in the UV there is no coincidence with the 290–300 nm maxima of the action spectra. The absorption of known photoreceptors is poor in the UV spectrum compared to the visible and it is difficult to see how the lesser absorption of these receptors in the UV at lower natural energies could influence their activity via the same induction pathway(s).

A study of responses of various ecotypes of Arabidopsis to UV-B[6] demonstrated a straight-line relationship between the growth rate of the control cohort and the level of inhibition induced in the UV-B treatment (see Fig. 3). This relationship indicates that the faster a plant grows the more susceptible it is to UV-B. Higher growth rates infer higher rates of cell division and it has been suggested that there might be a link between UV-B and inhibition of cell division.

Work with the Arabidopsis mutants hy 42.23N[3] also supports the concept of a specific UV-B receptor in that normal levels of CHS can be generated under UV-B for which there is no other explanation.

**TRANSDUCTION**

Pharmacological experiments designed to investigate the involvement of calcium in the signal transduction from UV receptors used cell suspensions of Arabidopsis, in which CHS was controlled in the same manner as in mature leaves.[3] Using nifedipine, ruthenium red, lanthanum, an ionophore, and the calmodulin antagonist W7 with UV-B and UV-A/blue irradiation, it is argued that calcium at a specific cellular location passes through calcium channels and causes a localised increase in calcium concentration. The calmodulin antagonist W7 strongly inhibits the UV-B induction but not the UV-A/blue induction of CHS transcript. This is in agreement with the genetic evidence that these signals are perceived by separate systems.

As mentioned above, irradiation of plants with UV-B can result in the generation of intracellular ROS (see Ref. 8), which can cause serious damage to membranes. However it has also been suggested that ROS can act as signaling intermediates and are involved in UV-B induced transcript increases in a number of photosynthetic proteins in various plants.[8] ROS may also function as secondary messengers acting up stream in a number of pathways including the synthesis of salicylic acid, jasmonic acid, and ethylene.[8]

**SIGNAL DAMPING**

CHS is a controlling enzyme in the production of flavonoids and phenylpropanoids. If these compounds are produced in the epidermal layers of the plant, they can efficiently absorb UV radiation while also allowing transmission of PAR. The study of Arabidopsis mutants deficient in various aspects of flavonoid and lignin synthesis has led to detailed knowledge of the regulation of the phenylpropanoid pathway and its role in plant defense against UV-B.[9] Mutants capable of tolerating high fluences of UV-B have been shown to be able to accumulate high levels of sinapate and flavonoids.[10]

Many of the nondamage plant strategies turned on by UV radiation would include reduction of leaf area, reduction in plant height, branching, and leaf number. These may all be interpreted as strategies that would reduce interception of radiation. Thus stimulation of receptors of UV may well function to produce screens and other developmental changes that would lead to reduced reception of harmful radiation.

INTRODUCTION

Triose phosphates produced by the Calvin cycle in the chloroplasts may be converted to starch or exported to the cytosol, where they synthesize sucrose to be transported to other parts of the plant. In this way, the pathways for sucrose and starch synthesis are separated in the cytosol and plastids and are fed by different hexose phosphate pools. The activity of the triose phosphate translocator (TPT)—located in the chloroplast inner membrane—is central in communicating the hexose phosphate pools of both compartments by exchanging the three carbon intermediates dihydroxyacetone phosphate (DHAP) and 3-phosphoglycerate (3PGA) for inorganic phosphate (Pi).

SUCROSE SYNTHESIS OCCURS IN THE CYTOSOL

Sucrose is a major product of photosynthesis and serves as the long-distance transport compound in most plants. Triose phosphates synthesized in the chloroplasts by the Calvin cycle are transported to the cytosol by the TPT where they produce hexoses and subsequent synthesis of sucrose.

Once in the cytosol, the combined action of triose-phosphate isomerase and fructose 1,6-aldolase converts triose phosphates to fructose 1,6-bisphosphate (F1,6BP). The interconversion of F1,6-BP and fructose 6-phosphate (F6P) involves the regulatory metabolite fructose 2,6-bisphosphate (F2,6BP) and three enzymes: ATP-dependent phosphofructokinase (PFK; F6P+ATP→F1,6BP+ADP), pyrophosphate-dependent phosphofructokinase (PFP; F6P+PPi→F1,6BP+Pi), and fructose 1,6-bisphosphatase (F1,6BPase; F1,6BP+H2O→F6P+Pi).1,11 PFK and F1,6Base are found in both the cytosolic and plastidic compartments in leaves but PFP occurs exclusively in the cytosol. PFP catalyzes a reversible reaction and is activated by F2,6BP in the direction of F1,6BP formation, although its direct role in controlling F1,6BP synthesis and degradation in vivo in leaves is still under discussion. PFK is inhibited by PEP and by other metabolites of the last part of the glycolytic pathway. In this way, this pathway is negative-feedback regulated, involving the function of the TPT, which means that if DHAP is supplied by the chloroplast, there is no need to generate F1,6BP through glycolysis (Fig. 1). Cytosolic F1,6BPase regulates the flow of carbon from the triose phosphate to the hexose phosphate pool. This enzyme is strongly inhibited by the metabolite F2,6BP, which is synthesized from F6P by fructose 6-phosphate 2-kinase and converted back to F6P by fructose 2,6-biphosphatase (Fig. 1). Fructose 6-phosphate 2-kinase is activated by Pi and F6P and inhibited by triose phosphates, in contrast to fructose 2,6-biphosphatase, which is inhibited by Pi and F6P. Hence, the concentration of F2,6BP is related to the activity of the TPT, which determines the concentration of triose phosphates and Pi in the cytosol. As the concentration of F2,6BP is controlled by the status of the triose phosphate pool, F1,6BPase is active only when carbon is supplied by the chloroplast (Fig. 1).

After converting triose phosphates to hexose phosphates, the principal route of sucrose synthesis combines the reactions of sucrose-phosphate synthase (SPS, UDP-glucose+fructose 6-P→sucrose 6-P+UDP) and sucrose-phosphate phosphatase, which has a large negative free energy change (sucrose 6-P→sucrose+Pi).12 The synthesis of UDP-glucose involves the action of the enzyme UDP-glucose pyrophosphorylase (G1P+UTP→UDP-glucose+PPi). In the absence of a cytosolic pyrophosphatase, the reaction is readily reversible. A second enzyme—sucrose synthase (UDP-glucose+Fructose→sucrose+UDP)—is capable of catalyzing both sucrose synthesis and degradation. Nevertheless, this enzyme predominates in sucrose-utilizing tissues and is more involved in sucrose degradation. SPS is regulated by both covalent modification and allosteric modulation. Glucose 6-phosphate (G6P) directly activates the enzyme and also inhibits a kinase that phosphorylates and down-regulates the activity of SPS, while Pi inhibits SPS and a phosphatase that up-regulates the activity of SPS (Fig. 1).

STARCH SYNTHESIS OCCURS IN PLASTIDS

When the synthesis of sucrose exceeds the capacity of the leaf to export it, synthesis of starch is used as an overflow mechanism to store carbohydrate. Triose phosphates in the chloroplast are converted to hexose phosphates, which form ADP-glucose to incorporate glucose to starch. The
enzyme that synthesizes ADP-glucose—ADP glucose pyrophosphorylase (Glucose 1-P+ATP → ADP-glucose +PPi)—is the regulatory enzyme in starch biosynthesis. A plastidic-specific pyrophosphatase cleaves pyrophosphate (PPi) driving ADP-glucose synthesis. In turn, starch synthase incorporates glucose from ADP-glucose to the nonreducing end of amylose or amylopectin chain, while a starch-branching enzyme produces 1→6α linkages. When chloroplastic 3PGA is abundant, ADP glucose pyrophosphorylase is activated. In contrast, when Pi concentration increases, the enzyme is inhibited (Fig. 1). Pi concentration can rise not only when photosynthesis slows, but also when the TPT is active in exchanging triose phosphate from the Calvin cycle by cytosolic Pi.

### INTEGRATED CONTROL OF SUCROSE AND STARCH SYNTHESIS INVOLVES TWO CELL COMPARTMENTS

Different processes tightly regulate the balance between sucrose and starch synthesis, which are both related with a constant sensing of metabolite levels in both the chloroplast and the cytosol. The balance between sucrose and starch synthesis varies during the day in response to different environmental conditions that regulate the rate of carbon assimilation and photosynthesis and sucrose transport.

At the beginning of the light period, the Calvin cycle becomes operational and triose phosphates accumulate in the chloroplast. This accumulation triggers the TPT to exchange triose phosphates by Pi, increasing cytosolic concentration of triose phosphates with a consequent decrease in Pi concentration. In turn, F2,6BP concentration decreases, relieving the inhibition of F1,6BPase. This allows the flow of carbon into the hexose phosphate pool (Fig. 1). The increase in G6P and decrease in Pi concentrations activate SPS, allowing the synthesis of sucrose to proceed. Meanwhile, starch synthesis is inhibited by high Pi and low PGA concentration in the chloroplast. Sucrose export is active in this condition (Fig. 2A).

When the increase in photosynthate exceeds the ability of the cell to export sucrose—which may occur at midday at high light conditions—starch begins to be synthesized from excess carbon. Concurrently, sucrose accumulation inhibits its own synthesis, hexose phosphates accumulate, and F6P induces F2,6BP synthesis (Fig. 1). The increase in this metabolite inhibits F1,6BPase, producing an accumulation of triose phosphates in the cytosol that slows the export from the chloroplast. 3PGA accumulates in the chloroplasts, activating ADP-glucose...
pyrophosphorylase and promoting starch synthesis (Fig. 1). Pi concentration in the cytosol increases as a result of decreased import into the chloroplast, which contributes to the inhibition of SPS and the increase in F2,6BP concentration. Hence, carbon flow is derived from sucrose to starch (Fig. 2B).

When light declines, the rate of photosynthesis slows, and with it the rate of sucrose synthesis. The decrease in 3PGA concentration in the chloroplasts no longer activates ADP-glucose pyrophosphorylase, which, in combination with Pi accumulation, induces the stop of starch biosynthesis. At this time, amylolytic and/or phosphorolytic starch breakdown is triggered. Triose phosphates are transported to the cytosol and F2,6BP decreases the amount of carbon (and hence, sucrose) allowed to flow into the hexose phosphate pool. Sucrose is then transported to other parts of the plant. In this condition, sucrose export exceeds the rate of synthesis (Fig. 2C).

**TRANSGENIC PLANTS WITH ALTERED SUCROSE OR STARCH LEVELS**

Transgenic plants with altered expression of the TPT have been developed. Potato plants with lower TPT activity presented increased starch levels, indicating a central role of the TPT in the flux of carbon into sucrose and starch.[4] Later, antisense TPT tobacco lines showed that the decrease in TPT levels could be compensated by high turnover of starch and subsequent glucose export from the chloroplast to the cytosol.[5] Recently, transgenic tobacco plants with antisense repression or overexpression of the TPT[6] were used to calculate control coefficients of the TPT on carbon partitioning and photosynthesis.[7] Under high CO2, tobacco plants with decreased or increased TPT activity presented, respectively, higher or lower carbon incorporation into starch.[6,7] Transgenic plants with altered amounts of F2,6BP have also been developed.[8,9] These plants have directly demonstrated the importance of this regulatory compound in the integration of cytosolic and chloroplastic metabolism during photosynthesis. Elevated F2,6BP levels reduced the rate of sucrose synthesis at the start of the light period, whereas a decreased content of F2,6BP promoted the partitioning of photosynthates into sucrose relative to starch, with a decline in the rate of carbon assimilation. In this way, decisive evidence was provided of the crucial role of F2,6BP in coordinating sucrose synthesis with the rate of carbon fixation and in regulating photosynthetic partitioning between sucrose and starch.

**APOPLASTIC OR SYMPLASTIC PHLOEM LOADING IN LEAVES DEPENDS ON THE SPECIES**

Sucrose synthesized in leaves is transported to the site of consumption and storage via the phloem. Phloem loading
in leaves may occur apoplastically or symplastically depending on the species. Anatomical features have been used to categorize plant species based on their mechanism of phloem loading. The symplastic path occurs via the plasmodesmata, which connects mesophyll cells and the conducting elements of the phloem. In the apoplastic route, sucrose is first exported into the apoplast and then is taken up by the phloem by an energy-dependent transport system.

Photosynthesis and Stress

Barbara Demmig-Adams
Volker Ebbert
William W. Adams III
University of Colorado, Boulder, Colorado, U.S.A.

INTRODUCTION

The impact of stress on photosynthesis can be viewed as the response of photosynthesis to environmental conditions outside the favorable range. For example, although differing greatly in their origin, the stresses of freezing temperatures, low water availability, and high salinity have a common impact in that they all result in low water availability to the plant. In response to this, stomates close to varying degrees and net carbon uptake declines. But what happens behind closed stomates? In some species, the decline of carbon uptake is due merely to a transient closure of stomates—with a full maintenance of internal maximal photosynthetic capacity. In other species, stomatal closure is accompanied by a downregulation of the internal maximal capacity of photosynthesis, including, e.g., the capacity of photosynthetic electron transport. In evergreens, this downregulation of electron transport capacity is typically accompanied by a phenomenon referred to as photoinhibition of photosynthesis.

PHOTOSYNTHESIS BEHIND CLOSED STOMATES

Whereas some species maintain their intrinsic photosynthetic capacity when stomates close under unfavorable environmental conditions, others downregulate it. Those species that maintain electron transport capacity use electrons in processes other than carbon fixation (such as photorespiration or oxygen reduction in the Mehler-peroxidase pathway). This offers the advantage that solar energy can still be used to provide some adenosine triphosphate (ATP) and reducing equivalents—even when there is little or no net carbon gain.

Other species suspend all photosynthetic activity when net carbon uptake ceases and strongly downregulate photosynthetic electron transport capacity. This strategy precludes any utilization of solar energy, but offers the advantage of effectively suppressing the transfer of electrons to potentially toxic superoxide (Fig. 1). This latter strategy necessitates an efficient dissipation of excess absorbed solar energy no longer used in photochemistry as harmless thermal energy (Fig. 2). In many evergreens, the utilization of solar energy in photosynthesis is strongly downregulated under environmental stress, yet the light-harvesting chlorophyll is preserved. This poses a potentially lethal danger in the form of energy transfer from chlorophyll to toxic singlet excited oxygen (Fig. 2). Such a transfer of energy from chlorophyll to singlet oxygen can be suppressed effectively by the harmless dissipation of this energy as thermal energy. The syndrome of persistently low utilization of absorbed solar energy in photosynthesis and highly efficient thermal dissipation is a key feature of the photoinhibition of photosynthesis under stress (Fig. 2).

PHOTOINHIBITION OF PHOTOSYNTHESIS

Photoinhibition of photosynthesis can occur in response to exposure to a wide variety of environmental stresses or to sudden increases in growth light intensity. The hallmark of photoinhibition is a combination of two features. First, a decrease in maximal electron transport capacity, resulting from inactivation and subsequent degradation of photosystem II centers. This is accompanied by a second feature—a switch to continuously high levels of harmless dissipation of a potentially lethal excess of light absorbed in the largely preserved light-harvesting antennae of photosystem II (Fig. 2). Whereas these features are generally accepted, current interpretations vary and range from viewing photoinhibition as reflecting damage to photosystem II centers on one hand versus downregulation of photochemistry in response to a low demand for photosynthate on the other. Some consequently predict an increase in photosynthetic productivity under stress if photoinhibition could be eliminated. It must be noted that those species exhibiting the strongest photoinhibition in the field are those that possess the highest levels of stress tolerance.

PERSISTENT AND FLEXIBLE FORMS OF PHOTOPROTECTION

In evergreens, the switch from utilizing solar energy in photosynthesis to dissipating it as heat can persist for an
entire unfavorable season. All species, however, utilize a flexible version of this process. All sun-exposed leaves reroute excess absorbed solar energy to thermal dissipation during peak exposure to direct sunlight, and return to efficient harvesting of solar energy for photosynthesis when light levels decline again.[7] The importance of this process is illustrated by the fact that mutants deficient in thermal dissipation have a reduced reproductive fitness.[8] The fraction of absorbed light allocated to thermal dissipation typically increases under a variety of environmental stresses.[7] Thermal dissipation is thus a key photoprotective mechanism in plants and counteracts the formation of toxic reactive oxygen when the utilization of solar energy in photosynthesis declines (Fig. 2).[1,3,9] In addition, all species also possess back-up mechanisms to detoxify reactive oxygen species once formed.[9]

**CONTRASTING ACCLIMATION PATTERNS IN SPECIES WITH DIFFERENT GROWTH FORMS AND LIFESPAN**

What are the reasons for species-dependent differences in stress response? The answer may lie in the degree to which growth processes and utilization of carbon are affected by environmental extremes in a given species. A key factor regulating maximal photosynthetic capacity is the demand for photosynthate at the whole plant level.[10] As long as photosynthate continues to be consumed in growth processes (i.e., sinks; Fig. 1), a high photosynthetic capacity is maintained. When unfavorable environmental conditions lead to a cessation of growth and carbon utilization, photosynthetic capacity is downregulated.

Different species vary in how strongly growth and carbon utilization respond to environmental change.

**Freezing Temperatures**

In seasonally cold climates, overwintering annual and biennial species exhibit different responses than overwintering long-lived evergreens. (Figs. 3–5). All of these species likely suspend net carbon uptake on subfreezing days. Annuals or biennials, on one hand, maintain intermittent growth as well as maximal photosynthetic capacity (Fig. 3, *Malva neglecta*; Fig. 4), and rapidly resume photosynthesis on milder winter days.[2] Some evergreens, on the other hand, cease growth for the duration of the winter, downregulate their maximal photosynthetic capacity (Fig. 3, Douglas fir; Fig. 5), exhibit strong photoinhibition, and remain photosynthetically inactive even on milder days.[2]

Why don’t all species exercise the same flexibility as the annuals and biennials? The acclimation patterns are apparently associated with lifespan. Species with a shorter lifespan tend to invest in maintaining growth and maximal photosynthetic capacities, whereas many species with a longer lifespan simply abandon growth and downregulate maximal photosynthetic capacity during unfavorable seasons. What might be the advantage of the latter strategy? The downregulating evergreens clearly possess a very high level of stress tolerance. Only species employing this latter strategy are found in extreme environments, such as above 3000 m in subalpine forests where soil water remains frozen throughout the winter.

*Fig. 1* Schematic depiction of photosynthetic reactions in leaves, including the absorption of solar energy and photosynthetic electron transport, formation of NADP and ATP, and uptake of carbon dioxide and its conversion to sugars. O$_2^-$ is superoxide, formed by transfer of an electron (e$^-$) to oxygen. *(View this art in color at www.dekker.com.)*
Contrasting strategies have also been observed under stress conditions other than freezing temperatures, such as low water availability at moderate temperatures. For species adapted to arid (dry) habitats, several principal response types have been described. Some species accumulate osmotically active substances to maintain water uptake from the soil (i.e., perform osmotic adjustment), and it is often thought that crop yield under drought may be increased by enhancing solute accumulation.\textsuperscript{[11]} However, osmotic adjustment may be beneficial only in combination with enhanced root development to allow access to water deeper in the soil.\textsuperscript{[11]} An important group of species (phreatophytes) native to arid environments use...
this strategy. But there are also cases where neither osmotic adjustment nor turgor maintenance takes place and strong photosynthetic downregulation and photoinhibition occur, such as in Nerium oleander that is native to seasonally dry environments. Salinity is another environmental factor leading to low water availability to the plant. Among species adapted to high levels of salinity (halophytes), different strategies can once again be observed. An example of a species with an extremely flexible strategy is Mesembryanthemum crystallinum (Fig. 6) that switches from C3 photosynthesis and rapid growth under more favorable conditions to slowed growth, enhanced succulence, and Crassulacean acid metabolism (CAM) under low water availability/high salinity. Other species, such as mangroves (Fig. 7), instead maintain low growth rates over a wide range of salinities and thermally dissipated a large fraction of the light they absorb when sun-exposed.

Low Nitrogen Availability

Photosynthetic response to low nitrogen availability has been studied extensively in annual species such as spinach.\textsuperscript{[12]} Nitrogen deficiency affects the growing points most severely and leads to stunted overall growth (Fig. 8). This results in severe sink limitation (cf. Fig. 1), and carbon accumulates in the photosynthesizing source leaves. This induces photosynthetic downregulation and favors remobilization of nitrogen from older source leaves to the growing points. Because the downregulation of photosynthesis affects both the capacity of light harvesting and electron transport, and the absorption of light thus decreases along with its utilization, photoinhibition typically does not occur in this species.

Although not studied in mechanistic detail, evergreens adapted to low-nutrient environments tend to exhibit less visible effects and can apparently remain green.
Exposure to High Light Levels

Annuals typically increase photosynthetic capacity with increasing growth light intensity, as long as other factors such as nitrogen availability are not limiting (Fig. 3, spinach). Evergreens tend to show less pronounced increases, even under favorable conditions (Fig. 3, Swiss cheese plant; Fig. 9), and instead exhibit strong increases in thermal dissipation of excess absorbed light and sometimes strong photoinhibition of photosynthesis.[4] The maximal photosynthetic capacities of the evergreens shown in Fig. 3 are much lower than those of the annuals and biennials. It appears that the life span of leaves is inversely related to maximal photosynthesis rate but positively related to the propensity for photoinhibition.

PHOTOSYNTHETIC PATHWAY AND STRESS RESPONSE OF PHOTOSYNTHESIS

As mentioned earlier, exposure to low water availability triggers a switch to CAM in M. crystallinum. Both C4 photosynthesis and CAM are characterized by a higher water-use efficiency and nitrogen-use efficiency than C3 photosynthesis, thus offering advantages when these factors are limiting.[13] In addition, both pathways confer a higher tolerance of high temperatures as a result of minimal photospiration rates and, in the case of some CAM plants, a higher intrinsic high temperature tolerance.

CONCLUSION

The response of photosynthesis to environmental stress clearly depends on species. Two contrasting examples are long-lived species that endure entire unfavorable seasons in a state of suspended growth and photosynthesis versus short-lived species that continuously maintain growth and photosynthesis but are limited to less extreme environments. Suspension of intrinsic photosynthetic capacity during adverse seasons is dependent on the downregulation of photochemical conversion of solar energy into high-energy electrons and the upregulation of photoprotective thermal dissipation of the absorbed solar energy.

Photosynthetic Pathways: Scarcity-Driven Evolution

Stan R. Szarek
Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION
An important adaptation to CO₂-limited photosynthesis was development of metabolic mechanisms to concentrate the substrate. CO₂-concentrating mechanisms (CCM) occur in cyanobacteria, algae, and land plants. Crassulacean acid metabolism (CAM) occurs within select land plants (e.g., orchids and cacti) in at least six different metabolic variations. A 40-fold increase in the CO₂ concentration within the cell containing ribulose bisphosphate carboxylase/oxygenase (RUBISCO) has been reported. Another CCM, dependent on activity of phosphoenolpyruvate carboxylase (PEPC), is C₄-type photosynthesis. This pathway, which includes four metabolic variations, occurs frequently within the grasses and sedges and achieves a 10-fold increase in the intracellular CO₂ concentration. Although most of the world’s crops lack a CCM, it may be possible to express the genes for CCMs in them and improve their photosynthetic efficiency.

ATMOSPHERIC CO₂
The raw materials for photosynthesis are radiant energy from the sun, water from the soil, and atmospheric CO₂. The first two are abundant relative to molecules of CO₂. Over the last 120 million years, the estimated concentration of atmospheric CO₂ has decreased from 0.3% (or 3000 μmol/mol) to 0.04% about 65 million years BP. Analyses of ice cores indicate that an even lower level, near 0.018%, occurred about 10⁵ years BP. The current scarcity of this gas, in addition to its physical features, makes CO₂ a limiting factor for photosynthesis. It has relatively low solubility in water, being about 15 μM at 15°C, and its solubility decreases with increasing temperature to about 9 μM at 35°C. This feature especially limits photosynthesis in high-temperature environments.

CO₂ ASSIMILATING ENZYME
Ribulose bisphosphate carboxylase/oxygenase (RUBISCO) functions as the fundamental enzyme for assimilating CO₂ in all organisms that perform oxygenic photosynthesis. The enzyme in chloroplasts is a 16-subunit protein that possesses novel features. Its affinity for CO₂, over that for O₂, has changed during the course of its evolution, being 8-fold higher in plants than in cyanobacteria. This differential affinity decreases as temperature increases. In addition, the current form of this carboxylase in plants has a relatively low kinetic efficiency ($K_m$ about 25 μM; $k_{cat}$=3 sec⁻¹ when fully activated) in relation to the concentration of dissolved, gaseous CO₂ in water 15 μM or less. Perhaps as a compensatory mechanism, this protein may constitute up to one-half of the leaf’s total soluble protein. Many researchers have reported that the rate of apparent photosynthesis by a C₃-type (see below) leaf correlates strongly with the amount of RUBISCO in that leaf.

PHOTOSYNTHESIS IN CYANOBACTERIA AND ALGAE
An important adaptation to CO₂-limited photosynthesis in cyanobacterial and algal ancestors of plants was development of a CO₂-concentrating mechanism (CCM). In recent years, multiple forms of CCMs have been reported. The cyanobacteria have acquired two different CO₂ transporters and two types of HCO₃⁻ transporters.[1] Transcription for one of the latter transport systems is induced under low CO₂ conditions. The cyanobacteria also possess carboxysomes, the site for CO₂ assimilation within the cell and the location for carbonic anhydrase. This enzyme regulates the CO₂/HCO₃⁻ interconversion for efficient photosynthesis. It is estimated that inorganic carbon concentrations at the site of RUBISCO approach 50 mM, about 100-fold more carbon than occurs in air-equilibrated water.

PHOTOSYNTHESIS IN LAND PLANTS
The photosynthetic mechanism common to the relatives of the mosses, ferns, conifers, and 85% of the world’s angiosperm flora is C₃-type photosynthesis. The occurrence of CCMs in this biochemical group is rare. Higher relative rates of CO₂ assimilation occur in a few C₄-type plants, such as cultivated sunflowers with high carbonic
anhydrase activity and some annual life-cycle plants from warm deserts that have large amounts of RUBISCO in their ephemeral leaves.

CO₂-CONCENTRATING MECHANISMS IN LAND PLANTS

Crassulacean Acid Metabolism

The diel change in the acid content within leaves of succulent plants was recognized more than 150 years ago. Subsequent microbiological research with propionic acid bacteria suggested a metabolic system that might be similar to the one operating in succulent plants that accounted for the nocturnal acidification. Pulse-chase studies with leaves exposed to ¹⁴CO₂ in the dark provided evidence, in 1958, that ¹⁴C was incorporated into malic acid. Much research has since confirmed and clarified the nature of this CCM specifically known as Crassulacean acid metabolism (CAM). Characteristics diagnostic for the occurrence of CAM include: stomata primarily open at night and closed during the day; metabolism occurring in large (200–500 μm in diameter) chlorenchyma cells; a massive nocturnal accumulation of malic acid; and net CO₂ assimilation during the nighttime.[2,3]

The nature of this CCM centers upon a cytosolic form for phosphoenolpyruvate carboxylase (PEPC). An inverse pattern of starch degradation and acid accumulation occurs during the nighttime. Starch degradation provides the carbon skeletons for PEP. With nocturnal opening of stomata, atmospheric CO₂ diffuses into the leaf (or stem). Some remains as dissolved CO₂, but the majority is transformed to HCO₃⁻, the latter being the substrate for PEPC. Carboxylation of PEP results in the synthesis of malic acid or malate²⁻.

Membrane transport studies suggest an ATPase at the tonoplast, pumping protons into the vacuole. A malate/H⁺ exchange, using a transmembrane protein in the tonoplast of CAM cells, may be coupled (directly or indirectly) to this proton pump. The existence of a K⁺/H⁺ symporter might also play a role in net malate influx. The accumulation of acid in the vacuole, a compartment that may constitute >95% of the cytoplasmic volume, approaches 500 mmol H⁺/m² of leaf (or stem) surface area. Malate accumulation continues until dawn when exposure to light triggers an acid efflux from the vacuole. The cytoplasmic compartment is then flooded with the organic acid, which acts as a “feedback inhibitor” of PEPC. There is also evidence that the Kᵢ and Kᵣm components of PEPC change on a diel basis, independent of malate exposure. Decarboxylation releases CO₂ from malic acid and, with daytime closure of stomata, intercellular CO₂ concentrations increase to levels >1%. By comparison, the internal CO₂ concentration in photosynthesizing leaves of C₃ plants has been estimated at 0.02–0.025% (or 200–250 μmol/mol).

Crassulacean acid metabolism represents a temporal separation for the carboxylation of atmospheric CO₂ (nighttime) and net carbon assimilation (daytime). The biochemical events occurring during the daytime are C₃-type: carboxylation of ribulose 1,5-bisphosphate (RuBP), via RUBISCO, to two trioses; reduction of 3-phosphoglyceric acid; and the regeneration of RuBP by the Calvin cycle. Some of the trioses are diverted for starch synthesis which increases in concentration during the daytime period.

The CAM pathway exhibits an extraordinary range of metabolic plasticity governed by environmental, developmental, tissue-specific, hormonal, and circadian cues.[3] In one subgroup, including Opuntia species when water-stressed, plants close their stomata for the entire 24-hr period. This condition persists until the next effective rain event, which may be a months-long period. There is a dampened level of acid accumulation but no net assimilation of atmospheric CO₂. This alternative to typical CAM has been called CAM-idling. The plants stay alive, and perhaps reduce photooxidative damage,[4] by recycling the internally generated CO₂.

A second subgroup—those known as CAM-cycling plants—functions as C₃-type photosynthetic plants when there is ample water in the soil. When water becomes limiting for absorption and tissue water potentials decrease, stomata close throughout the diel period and CAM-idling ensues. This photosynthetic flexibility occurs in leaf succulent plants, e.g., Pereskia, Talinum, and Cissus.[5]

A third subgroup is based on evidence for a morphological partitioning of CAM and C₃-type metabolism within a single species. During the wet season, a plant may produce ephemeral leaves which demonstrate only C₃-type features. The stem, in both dry and wet periods, functions as CAM only. This phenomenon has been reported in Frerea, Euphorbia, and Pachypodium. In rare cases, e.g., Portulaca species, C₄ and CAM-cycling co-occur in leaves, but CAM-idling can be induced in stems.[6]

A fourth subgroup demonstrates an anatomical partitioning of CAM and C₃-type metabolism within a single leaf. The middle mesophyll cell layer of Peperomia leaves expresses the gene for RUBISCO, has light-dependent CO₂ assimilation, and has no diel flux of acidity. In contrast, the mesophyll cells at the lower (adaxial) surface of the leaf solely express the gene for PEPC, demonstrate nocturnal CO₂ assimilation, and have a significant diel flux of acidity.

An additional subgroup includes those CAM plants that change the type of photosynthetic metabolism during the ontogeny of a single individual. Early in plant
development, young cacti and \textit{Peperomia} spp. function as C$_3$-type plants. As the plants age, the entire specimen shifts to a CAM mode of growth.

Photoperiodism has a regulatory role in short-day plants of \textit{Kalanchoe}, inducing a circadian rhythm in the activity of PEPC.

With all this metabolic flexibility in expressing CAM, it is not surprising that a polyphyletic origin has been proposed for CAM. This type of CCM has been reported in four different taxonomic orders, including the Lycopsida (isotyes), Filicopsida (ferns), Gnetopsida (welwitschia), and Anthophyta (flowering plants). Among the latter group, there are at least 21 dicot families as well as 8 monocot families. One study suggests that at least 25,000 species possess this CCM. The four plant families having the largest number of probable CAM plants are the orchids (epiphytic), the cacti, the crassulaceous plants, and the bromeliads (epiphytes), in a decreasing order for number of taxa. Agronomically important CAM plants include \textit{Agave} spp., pineapple, and the opuntias.

\textbf{C$_4$-Type Photosynthesis}

A second CCM, revealed by pulse-chase studies with $^{14}$CO$_2$, also produces a 4-carbon, initial product during daytime CO$_2$ assimilation. The molecule is either malic acid or aspartic acid (hence its description as C$_4$-type photosynthesis). The initial carboxylation of atmospheric carbon (as HCO$_3^-$) is also catalyzed by cytosolic PEPC in a chloroplast-containing mesophyll cell (MC). The 4-carbon molecule then diffuses into an adjacent bundle sheath cell (BSC), wherein a decarboxylase reaction releases CO$_2$, with a turnover time for $^{14}$C-malate near 2 sec. The ancestral carboxylase RUBISCO, localized exclusively in the chloroplast of BSC, then initiates a C$_3$-type photosynthetic carbon reduction.

The C$_4$ isofrom for PEPC may have evolved from one of two C$_3$-type isofroms.\cite{7} The first is a light-activated, cytosolic enzyme with greater tolerance toward malate. PEPC is more nearly saturated with its substrate (HCO$_3^-$) than RUBISCO. Although its $K_m$ is near 25 \textmu M, the dissolved bicarbonate concentration (equilibrated with air at cellular pH) is near 460 \textmu M. As such, the CO$_2$ delivered to the BSC approaches concentrations about 10-fold greater than the CO$_2$ concentrations at the site of carboxylation in C$_3$-type plants. The elevated levels of CO$_2$ in BSC increase the proportion of carboxylase to oxygense activity by RUBISCO.\cite{8} The specific localization of PEPC in the MC,\cite{9} which surround the BSC, decreases CO$_2$ efflux from the leaf that would result from any photorespiration occurring in the BSC. These features promote a higher rate of net CO$_2$ assimilation in the leaves of C$_4$-type plants, relative to that in C$_3$-type plants. This is especially true in high-temperature environments as the affinity of PEPC for its substrate is less affected by temperature than is RUBISCO. This CCM is also advantageous when carbon acquisition is limited by drought and salinity\cite{10} and when nitrogen is limiting.\cite{11}

Characteristics diagnostic for C$_4$-type photosynthesis include: presence of chlorenchymatic Kranz anatomy in the leaf; a spatial separation of carboxylation (in the MC) and net carbon assimilation (in the BSC); >95% of the initial $^{14}$C-label in a 4-carbon molecule; and close vein spacing. Various subgroups within C$_4$-type photosynthesis have been reported, including those defined by or containing the following:

1. The type of decarboxylase enzyme for processing malate (or aspartate) in BSC
2. Lacking Kranz anatomy but having C$_4$ biochemical features, e.g., \textit{Salsola kali} and some \textit{Orcuttia} grasses\cite{12}
3. C$_3$-C$_4$ intermediates defined either by anatomy and/or biochemistry, e.g., many \textit{Flaveria} spp.
4. C$_4$-type photosynthesis through spatial compartmentation of photosynthetic enzymes by separation of two types of chloroplasts and other organelles with the cytoplasm of a single chlorenchyma cell\cite{10}

Paleobotanical evidence points toward the origin of the angiosperms at about 130 million years BP. Evidence from fossil anatomical, paleopalynological, and paleocarbonate studies suggest an origin for C$_4$-type photosynthesis about 5–7 million years BP. Molecular sequence comparisons push the origin back another 10–13 million years. The origin of C$_4$ from C$_3$\cite{13} is also polyphyletic as eight taxonomic orders contain C$_4$ plants. The estimated number of individual plant species in this group may be 8000–10,000. The taxonomic families with the highest number of C$_4$ species are the grass, sedge, and chenopod taxa.

Agronomically important C$_4$-type plants include corn, sorghum, sugarcane, millets, and various pasture grasses. Many of the worst weedy species are C$_4$-type plants, including Bermuda grass, purple nutsedge, jungle rice, and barnyard grass. Although most agronomically important crops are C$_3$-type plants, research has been initiated to express corn genes in transgenic rice with the goal of increasing the photosynthetic efficiency of C$_3$-type plants.\cite{14}

A comprehensive review of C$_4$ photosynthesis is the work by Sage and Monson.\cite{15}

Photosystems I and II Structures

Andrew N. Webber
Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

The most fundamental recent advances in our understanding of the molecular mechanism of photosynthesis come from the application of X-ray crystallography and electron microscopy to develop detailed three-dimensional models of many of the photosynthetic membrane protein complexes. Photosystem II (PSII) and Photosystem I (PSI) are reaction center complexes found in chloroplasts that capture light energy and initiate photosynthetic electron transfer. Although many biochemical aspects of the mechanism of action of each complex have been worked out by careful experimental analysis, there are still many questions as to how these complexes are organized such that they can perform complex biochemical tasks. In this section, the most recent information on the structure of PSII and PSI will be overviewed.

PSII

The structure of the PSII complex isolated from the thermophilic cyanobacterium *Synechococcus elongatus* has been solved to a resolution of 3.8 Å.[1,2] This PSII complex is composed of at least 17 subunits, which include 14 intrinsic membrane proteins and three extrinsic subunits located on the lumenal side. The membrane intrinsic part of PSII consists of 36 transmembrane α-helices, of which 22 are assigned to D1, D2, CP43, and CP47, and are arranged with a local pseudo-twofold symmetry (Fig. 1).

Two groups of five transmembranes spanning α-helices, arranged as interlocking semicircles and assigned to α-helices A–E of the D1 and D2 subunits, form the reaction center heterodimer. This arrangement of the D1 and D2 subunits resembles that of the L and M subunits of the purple bacterial reaction center, and also the five C-terminal α-helices of the PsaA and PsaB subunits of PSI. Each of the CP43 and CP47 subunits, which are “core” antenna chlorophyll–protein complexes, consists of six transmembrane α-helices and flanks both sides of the D1/D2 subunits (Fig. 1). The structure of CP43 and CP47 is similar to the arrangement of the six N-terminal helices of the Psaa and Psab subunits of PSI. CP43 has been assigned to the subunit closest to D1, and CP47 has been assigned to the subunit closest to D2, based on earlier chemical cross-linking studies. CP43 and CP47 make up the internal antenna comprised of 12 and 14 chlorophyll a molecules, respectively. The chlorophyll a molecules form two layers close to the luminal and stromal sides of the membrane.

The electron transfer chain cofactors form two branches on either side of the pseudo-C2 axis and are assigned to the D1 and D2 subunits by analogy to the purple bacterial reaction center. Toward the luminal side, two chlorophylls with a Mg–Mg distance of 10 Å may represent the reaction center primary donor P680. This distance is quite large compared to other reaction centers, and suggests that excitonic coupling is relatively small and that each chlorophyll may be considered as a monomer. Two chlorophylls further toward the stromal side of PSII and located 9.8 and 10 Å from the primary donor chlorophylls are analogous to the accessory chlorophylls of the purple bacterial reaction center. They are followed by two pheophytin molecules, PheoD1 and PheoD2. The final electron acceptor, the tightly bound QA, is located 12 Å from PheoD1. The putative binding site of the mobile QB is unoccupied in the crystals. Two additional chlorophylls associated with the D1 and D2 subunits are assigned to ChlZD1 and ChlZD2.

The redox-active tyrosine, Tyr 161 of D1, bridges electron transfer between the manganese cluster and P680. A protrusion of the electron density in the last turn of the lumenal side of helix C in D1 may represent Tyr 161 at a distance of 7 Å from the manganese cluster.[1] The manganese cluster itself is located on the luminal side and is about 15 Å off of the C2 axis. A detailed understanding of the manganese cluster must await a higher-resolution structure. In addition, the presence of Ca2+ ions, which are important for water oxidation, was not observed.

PSI

The structure of the trimeric PSI complex from *S. elongatus* has been solved at 2.5 Å.[3] In the electron density map, 11 subunits could be identified. Ten of these were identified with known amino acid sequences.
However, the PsaK subunit was not well resolved, and the 12th subunit matched the amino acid sequence of PsaX, a subunit only identified in a few PSI preparations. Together with the 12 protein subunits, PSI also contained 127 cofactors comprising 96 chlorophylls, 2 phylloquinones, 3 Fe₄S₄ clusters, 22 carotenoids, 4 lipids, and 1 putative Ca²⁺ (Fig. 2).

The PsaA and PsaB subunits each contains 11 transmembrane α-helices that are divided into an amino terminal domain of six α-helices (A/B-a to A/B-f) and a carboxy-terminal domain of five α-helices (A/B-g to A/B-k). The carboxy-terminal domains enclose the cofactors of the electron transfer chain and are organized in a manner very similar to D1 and D2. The amino terminal domain α-helices are organized in a fashion similar to CP43 and CP47.

On the stromal side of PSI, the interhelical loops connecting the transmembrane α-helices partly constitute the binding site for the PsaC, PsaD, and PsaE subunits. The electron transfer chain of PSI is comprised of six chlorophylls, two phylloquinones and an Fe₄S₄ cluster. The chlorophylls and the phylloquinone are arranged in two branches related by a pseudo-C2 symmetry and coordinated by the five carboxy-terminal helices of PsaA and PsaB (Fig. 3). The cofactors forming either the A branch or the B branch are not exclusively bound by PsaA or PsaB because the A side accessory chlorophyll is bound by the B subunit and vice versa.

The primary electron donor P₇₀₀ is formed by the excitonically coupled chlorophyll pair eC-A₁/eC-B₁. The two chlorin rings overlap, are separated by an interplanar average distance of 3.6±0.1 Å, and are orientated perpendicular to the membrane plane. P₇₀₀ is, in fact, a heterodimer, with eC-B₁ being a chlorophyll a and eC-A₁ being a chlorophyll a'—the C₁₃² epimer of chlorophyll a. Chlorophyll a' also participates in hydrogen bonds from amino acid side chains and water[3–5] (Fig. 4). The 13¹-keto carbonyl oxygen at ring E is the acceptor of a hydrogen bond from Thr (A743). The phytyl ester carbonyl oxygen is a hydrogen bond partner of Tyr A735. In addition, the carboxy ‘‘ether’’ oxygen of the 13²-carbomethoxygroup is hydrogen-bonded by water. Three amino acids [Tyr(A603), Ser(A607), and Thr(A743)] are also putative hydrogen bond partners with this water molecule, but they cannot be assigned for certain because the H-bonds are not observable by X-ray diffraction. The H-bond to the 13²-carbomethoxy group may be one of the factors that stabilizes the incorporation of chlorophyll a' into the PsaA site.[4] The hydrogen-bonding pattern has important implications for the electronic structure of P₇₀₀ as the electron spin density should be located preferentially toward the non-H-bonded chlorophyll eC-B₁, in agreement with electron paramagnetic resonance spectra and electron nuclear double resonance studies.

Fig. 1  Structure of PSII. (a) Arrangement of transmembrane α-helices and cofactors in PSII. The view direction is from the lumen side, perpendicular to the membrane plane. (b) Side view of the monomer looking down the long axis of the D1 and D2 subunits. (From Ref. [1].) (View this art in color at www.dekker.com.)
indicating that at least 80% of the spin density is located on the chlorophyll ligated by PsaB.\[4\]

Toward the stromal side, a second pair of chlorophylls may be analogous to the accessory chlorophylls of the purple bacterial reaction center. The central Mg of these chlorophylls is ligated by water molecules hydrogen-bonded to an Asn of PsaA or PsaB.

The third pair of chlorophylls, eC-A3 and eC-B3, probably represents the electron acceptor $A_0$. These chlorophylls are coordinated by sulfur atoms provided by Met A688 and Met B668. Such coordination of a hard acid such as $\text{Mg}^{2+}$ by a soft base such as S is unusual and could contribute to the unusually low redox potential of this chlorophyll.\[5\] This possibility is supported by the fact that site-directed mutations that change the axial ligand to one that should better coordinate the chlorophyll, such as His, block forward electron transfer from $A_0$ to the phylloquinone.

One or both of the phylloquinones Qk-A and Qk-B may correspond to the electron acceptor $A_1$. The issue of whether one or both quinones are reduced and pass electrons to the iron–sulfur center $F_F$ is still an area of considerable controversy and has functional implications as to whether either or both branches are involved in electron transfer. Kinetic measurements indicate that

\]

\[\text{Fig. 3} \quad \text{The cofactors of the PSI electron transfer chain. The pairs of chlorophylls and phylloquinones are arranged in two branches (A or B) and are labeled with the letter A or B, indicating whether they are coordinated by the PsaA or the PsaB subunit. The center-to-center distances between the cofactors are given in angstroms. (From Ref. [3].) (View this art in color at www.dekker.com.)}\]

\[\text{Fig. 2} \quad \text{Structure of the PSI trimer from S. elongatus viewed normal to the membrane from the stromal side. Stromal subunits have been omitted for clarity. Different structure elements are viewed in each of the three monomers (I, II, III). (I) Arrangement of the transmembrane spanning $\alpha$-helices. (II) Includes also the interconnecting stromal and luminal loops. (III) Includes the cofactors associated with the intrinsic membrane proteins. The chlorophylls and quinones of the electron transfer chain are shown in blue, and the iron–sulfur centers are shown as orange and yellow spheres. (From Ref. [3].) (View this art in color at www.dekker.com.)}\]
electron transfer across the B branch is nearly 10 times more rapid than across the A branch.

CONCLUSION

The structures of PSI and PSII have provided detailed information on the way that light harvesting and electron transfer cofactors are organized. Improved structural resolution of the PSII complex will lead to a more complete view of the water-oxidizing complex that should answer many questions about its mechanism. The future challenge lies in attempting to understand the way in which the protein environment modifies the properties of the different cofactors so that they are able to perform their specific tasks. In particular, questions pertaining to redox properties of specific chlorophylls and quinones, and questions relating to what factors determine the directionality of electron transfer, can now be addressed based on the detailed structural information.

Photosystems: Electron Flow Through

Arlene Haffa
Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION
The capture of photons and their conversion into an energy form that can be stored and utilized later is the purpose of photosynthesis. Photosynthesis requires electron transfer reactions through photosystems to transduce photon energy to a charge-separated state, the power of which drives the synthesis of organic compounds useful for further chemistry. This transduction requires that the process be fast enough and the involved sites sufficiently spatially separated to prevent charge-separated states from recombining back into charge-neutral states before they are utilized. The segregation of charge is accomplished via a series of oxidation-reduction reactions through several pigment-protein complexes. In plant chloroplasts, electrons are transferred through two pathways: a linear noncyclic series of electron carriers that connect the beginning and the end of the system, and a cyclic pathway that operates around the second half of the system.

ELECTRON TRANSFER REACTIONS
Electron transfer involves an oxidation/reduction reaction (redox for short). One molecule yields an electron and is called the donor (D). A different molecule receives the electron and is called the acceptor (A). D becomes electron deficient, i.e., is oxidized and becomes a cation. A is reduced and becomes an anion. D has a more negative redox potential, i.e., it gives up an electron more readily than A. In photosynthesis, energy for the first reaction, which excites the donor with the most negative redox potential, is provided by photon energy and is called a photochemical reaction. Excited electrons are then transferred to a series of compounds with increasingly more positive (i.e., more easily reduced) redox potentials. This process is energetically downhill and does not require additional light but, along with the first reaction, is collectively called the light reactions. Good photon absorbers typically have conjugated double bonds, i.e., alternating single and double carbon-carbon bonds. A single photon that has the proper energy to excite an electron can move the electron from a lower to a higher energy orbital. If electron transfer occurs before the excited molecule relaxes to the ground state, then the excited molecule (D*) gives the electron to an acceptor (A). This can be written as:

\[ D \xrightarrow{\text{photon}} D^* \rightarrow D^+ + A^- \]

D is the primary donor. If conditions are energetically favorable, A can transfer its electron to another nearby molecule. A is referred to as the primary acceptor and the next molecule to receive the electron is a secondary acceptor.

ELECTRON TRANSFER REACTIONS IN PLANTS
Primary electron transfer in photosystems occurs in pigment-protein complexes called reaction centers. The proteins hold the pigments at proper distances and orientations for these reactions and also create electrostatic fields that make the reactions energetically possible. Exitonic energy arrives at the reaction center via an antenna complex where it excites two closely positioned chlorophyll \(a\) molecules, an arrangement referred to as the special pair (P, or the dimer). Plants have two types of reaction centers called Photosystem I (PSI) and Photosystem II (PSII). The special pairs of these photosystems are called P700 and P680, respectively, based on the wavelength of light necessary to excite them. Both P700 and P680 are on the lumenal side of the thylakoid membranes of higher plants, which is important for creating charge-separated states and proton-motive forces. The entire photosynthetic electron transfer chain also includes a cytochrome \(b_{6f}\) complex, which does not directly require a photon to initiate the electron transfer process. Many types of bacteria are capable of performing photosynthesis with only one photosystem.[1]

NONCYCLIC OR LINEAR ELECTRON TRANSFER
Electron flow through both systems is called noncyclic, or linear, because it is a one-way flow via the three major complexes of the photosynthetic chain: PSII, the cytochrome \(b_{6f}\) complex, and PSI (Fig. 1). Plastoquinone (PQ)
and plastocyanin (PC) act as shuttles between the first and second and the second and third complexes, respectively. When PSII donates an electron to the electron transport chain that connects the photosystems, it regains electrons by oxidizing water to produce oxygen. PSI donates electrons to NADP⁺ to produce NADPH, and regains its electrons from the electron transport carrier plastocyanin.

The first electron transfer within the reaction center of PSII is from P680 to a pheophytin (a chlorophyll molecule lacking the central Mg atom), which occurs in several picoseconds. Electrons are subsequently transferred to quinone acceptors (first QA then QB) over longer time scales (hundreds of picoseconds and then microseconds) toward the stromal side of the membrane. QB is

![Diagram of electron flow](image1)

**Fig. 1** Linear electron flow from water to NADP⁺ and the creation of a proton-motive force. Abbreviations are given in the article. (Created using information from Refs. 2–4 and 8–10.)

![Diagram of Z-scheme](image2)

**Fig. 2** Z-scheme depicting electron flow in plant photosynthesis from water to NADP⁺, showing relative energies of pigments along the transfer pathway that make the process thermodynamically favorable. (From Ref. 2.)
not permanently fixed in PSII and is generally called plastoquinone (PQ) when it is not associated with PSII. For simplicity only PQ is used in Fig. 2. Each PQ molecule requires two electrons and two protons to become reduced, which is therefore a two-photon process. Before the second photon can excite P680, the reaction center is brought from an oxidized state back to the ground state by an electron from water via an oxygen-evolving complex (OEC), and a tyrosine residue (Tyr) on one of the protein subunits. After full reduction (PQ+2e−+2H+→PQH2), PQH2 leaves PSII, and the binding site is refilled by an unreduced PQ from the plastoquinone pool in the membrane. PQH2 transfers its electrons to a cytochrome b6f complex. One electron is transferred to a cytochrome b (b1 for low then b2 for high energy) through the Q cycle and the other is transferred to a Rieske Fe-S center that participates in the linear electron transport. Electron transfer from PQH2 to the cytochrome complex is accompanied by proton release. The protons, which were taken from the stromal side of the thylakoid membrane, are released on the luminal side, forming a proton-motive force. The potential energy in the proton-motive force is used to drive conversion of ADP to ATP by ATP synthase. The electron on the Rieske center is transferred from an iron (Fe) atom in the iron-sulfur complex to plastocyanin, located on the luminal side of the complex. Plastocyanin leaves the complex and docks on PSI where it transfers an electron to P700+, reducing it to P700.

Electron transfer through PSI is similarly initiated by a photon. P700 transfers an electron to A0 (a chlorophyll a molecule), which then transfers it to A1 (a phylloquinone). A0 and A1 designate the primary and secondary electron acceptors. The electron is then passed through bound iron-sulfur centers (F_X to F_A to F_B) to a ferredoxin (Fd), which is soluble. Ferredoxin then transfers the electron to an NADP+ reductase, which completes the electron flow by reducing NADP+ to NADPH.

The Z-scheme (for zigzag) is a description of electron flow in photosynthesis from water to NADP+ (Fig. 2). It provides information about the energetics of the pigments in the electron transfer chain.

**REACTION CENTER STRUCTURE/FUNCTION**

The fundamental cores of PSI and PSII consist of symmetrically arranged cofactors imbedded in a dimer of protein subunits. Although there is symmetry in the arrangement of the photosynthetic cofactors, experiments suggest that electron transfer occurs primarily down one side of the reaction center. The symmetry is broken by differences in amino acids in the protein subunits. These differences alter the redox properties of the cofactors and dictate the directionality of the electron transfer reactions.

A detailed understanding of the exact electron transfer mechanisms in PSII has not been elucidated. Evidence for electron transfer occurring down one side of PSII has traditionally been extrapolated from bacterial reaction centers of purple nonsulfur bacteria. In the bacterial reaction center, the sides are called A and B, but the basic overall structure—although simplified and incapable of oxidizing water—possesses homology to PSI. Numerous spectroscopic experiments on the femtosecond timescale have been performed. Although the structure is symmetrical, only the A side is observed as active under normal physiological conditions. One exception is the high energy excitation that results (lifetime <15 ps) in B-side charge separation using the B-side accessory bacteriochlorophyll as the primary donor. Advances in the purification of PSI and experimentation on these pigment/protein complexes leads to the same conclusion in this photosystem (i.e., there is an active and an inactive branch). The spectral properties of PSI differ from those of the bacterial reaction center, however, and the mechanism of electron transfer may be different.

PSI also possesses an approximate symmetry. Experiments on PSI have not led to a clear conclusion as to whether one or both of the electron transfer pathways is used. Data suggest that electron transfer may occur on both sides, but one side seems to be kinetically much faster. Electron transfer on the slower branch cannot be observed without somehow impairing the faster branch.

**CONCLUSION**

The study of electron flow through photosystems has revealed that plants are capable of utilizing either linear or cyclic electron transfer pathways to convert light into stored energy forms. The two systems allow plants to adapt to a variety of environmental conditions. Primary charge separation reactions occur in symmetric pigment/protein complexes called reaction centers. Further study is needed to determine how the symmetric structure of the reaction center relates to its function.

Phyllosphere Microbial Diversity

Mark J. Bailey
Ian P. Thompson
Tracey M. Timms-Wilson
Centre for Ecology and Hydrology, Oxford, U.K.

INTRODUCTION

The phyllosphere is an exposed habitat prone to physical and chemical extremes that impose considerable selective pressures on resident communities, resulting in fluctuations in both the diversity and density of microbial populations. This variable and unbuffered nature makes the study of plant surface microbial ecology particularly challenging. Not least as airborne and water splash deposition of microorganisms on plant surfaces confuses the differentiation between true phyllosphere colonists and airborne surface contaminants. Nutrients, including amino acids, carbohydrates, or organic acids, and water can be limiting on the leaf surface. However, additional nutrients can diffuse via the waxy cuticle particularly after damage following infection or ageing. In addition, temperature, ultraviolet (UV), and infrared radiation fluctuate diurnally and directly affect the biota on the upper (adaxial) surface of the leaf. These biotic and abiotic factors all expose microbial communities to extreme stress that require resistance or tolerance mechanisms to aid survival. It is therefore apparent that bacteria, yeast, and fungi, which colonize aerial plant surfaces, must be specialists that have adapted to life at the edge. In the following sections there follows a brief synopsis of the approaches that are available to determine the diversity of phyllosphere microbiota and the molecular basis of their adaptation to life at the leaf.

THE PHYLOSSPHERE

The surface and interior of aerial parts of plants are defined as the phyllosphere, which represents the habitat for many microbial communities. Bacteria are by far the most abundant colonizers, typically with community densities of $10^7$ cells per cm$^2$ of leaf surface.$^{[1]}$ Leaves and flowers often form very complex shapes forming what is probably the largest biotic surface area on the planet on which microbial colonization can occur. These “epiphytic” microorganisms utilize exudates from the leaves and other aerial parts of the plant. Although many phyllosphere microbes form an apparently commensal relationship with the plant leaves, numerous interactions are mutualistic and/or parasitic.

METHODS TO MEASURE MICROBIAL DIVERSITY

Table 1 shows a list of typical bacterial species recorded in the phyllosphere. Many approaches have been employed to examine phyllosphere microbial community composition. In general, abundant species are often detected easily, whereas those with small population sizes are more difficult to detect; thus the appropriateness of detection methods is important. While cultivation-based methods have provided a great deal of knowledge concerning the distribution and physiology of microorganisms, their general usefulness may be limited because of bias, incompleteness, and time constraints. Some of these limitations have been overcome in recent decades by adopting nucleic acid-based techniques. However, all techniques have their own advantages and limitations, and the use of complementary approaches will undoubtedly provide a more complete picture of microbial community dynamics than any single technique alone.

Culture-Based Methods

This approach is based on the isolation and growth of microorganisms in the laboratory. Individual colonies are isolated on solid agars containing nutrients; the choice is operator dependent. Media have been developed that enable selective growth of specific populations either by modifying nutrient composition, by inclusion of inhibitors, or by incubation conditions. For enumeration it is assumed that each colony is formed from a single cell. All culture conditions are selective for those microorganisms that are able to grow under the specific artificial environment provided. Thus one can increase the coverage of plate count techniques by using several media, each of which selects for a separate fraction of the community. However, it is estimated that only 1% to 10% of the total microbial community$^{[2]}$ can be grown using contemporary methods of isolation. The plate count

(Continued)
technique depends on the cultivation of the microorganisms on the media used, and selectivity therefore depends on the composition of the medium. Less selective media can be used for “total viable and culturable” counts, e.g., Luria–Bertani (LB) medium. Miller et al. showed that the highest number and largest diversity of soil bacteria were found when using a relatively nutrient-poor medium such as R2A (Difco, Oxoid). Once pure cultures have been obtained, a number of methods are available to identify the species diversity represented. Metabolic and molecular techniques have been employed including BIOLOG, restriction digestion or sequencing of 16S rRNA genes, enterobacterial repetitive intergenic consensus sequence–PCR (ERIC-PCR), random amplified polymorphic DNA (RAPD), fatty acid methyl esters (FAME) analysis, multilocus enzyme electrophoresis (MLEE), fluorescence in situ hybridization (FISH), rDNA intergenic spacer analysis (RISA), and length heterogeneity PCR (LH-PCR).

### Culture-Independent Methods

Molecular techniques have revolutionized our ability to describe the diversity of communities, predominantly on the basis of 16S ribosomal RNA gene phylogeny. An advantage of molecular techniques is that they can be developed to analyze the total nucleic acid fraction (DNA and/or RNA) extracted directly from the environment. Methods include reverse array hybridization and clone library screening, PCR-based community profiling techniques such as denaturing gradient gel electrophoresis (DGGE) and temperature gradient gel electrophoresis (TGGE), and single-strand conformation polymorphism (SSCP). Other methods based on PCR include amplified ribosomal DNA restriction analysis (ARDRA), terminal restriction fragment length polymorphism (T-RFLP), and LH-PCR, which are based on enzymatic digestion of PCR-derived amplimers with restriction endonuclease enzymes. In one of the first applications
of its kind,\(^4\) DGGE-16S rRNA gene analysis was applied to describe the total diversity of phyllosphere communities. Related studies\(^5\) confirmed their findings that many previously described bacterial genera are abundant and that few novel taxa were detected. As seen in rhizosphere studies, phyllosphere diversity varies between plant species and time of sampling.\(^{21}\) but leaf-associated communities are less complex.

**POPULATION DYNAMICS**

The size and nature of the phyllosphere microbial community are not only a reflection of the host plant physiology and local environmental conditions, but also the phenotypic and genotypic plasticity of local microbial populations and how they adapt to change.\(^{22}\) If a population cannot adapt it will be outcompeted by succeeding groups, this event may be dynamic, and diurnal cycles as well as seasonal cycles of succession have been observed. In a study of the seasonal changes seen in the phyllosphere of sugar beet,\(^3\) the greatest microbial numbers were detected on senescing primary leaves, and fluctuations in numbers of filamentous fungi, yeast, and bacteria were similar on senescent primary, mature, and immature leaves. This study also showed that the phyllosphere is a highly selective habitat for microorganisms, with as few as 13 bacterial species on each leaf type throughout a growing season, and the bacterial community on any given leaf type on a given day was usually numerically dominated by one or five other species. Bacterial community diversity was at its lowest mid season correlating with the warmest driest weather, and at its highest near the end of the season when rainfall was high and temperature low. Other studies on sugar beet have shown bacterial proliferation and recolonization from season to season, emphasizing the point that phyllosphere colonists are specialists.\(^{23}\) These observations have led to more detailed molecular investigations to establish whether bacteria colonizing aerial plant surfaces carry novel genes specific to that habitat, and how bacteria perceive the habitat and regulate adventitious gene expression.

**Reporter Genes and IVET to Identify Cellular Activity and Novel Traits In Situ**

In vivo expression technology (IVET)\(^{24}\) is a gene fusion technology where ecologically significant genes can be identified on the basis of their positive contribution toward a specific phenotype. In vivo expression technology has been used to study environmentally significant genes expressed in the phyllosphere by nonpathogenic-plant-associated bacteria such as *Pseudomonas fluorescens* SBW25.\(^{25}\) SBW25 has been shown to carry genes that are induced only in the phyllosphere.\(^{20}\) In related activities, phyllosphere bacteria have been genetically modified to carry reporter genes (*lacZY, lux, gfp*) that are either constitutively expressed or placed under the control of inducible promoters, to facilitate the monitoring of bacterial colonization and activity.\(^{27}\) They have also been used as bioreporters to determine the presence of specific carbon sources or effectors including fructose and sucrose\(^{13}\) and Fe\(^{3+}\)\(^{28}\) in pseudomonads. Other systems have also been adopted to study the rate of gene transfer on leaf surfaces. These include the work of Bjorkof et al.\(^{29}\) and Normander et al.\(^{30}\) who monitored plasmid transfer between introduced inocula and the work of Lilley and Bailey\(^{31}\) who recorded seasonal influences on the initiation of plasmid transfer between natural populations and the fitness advantage plasmids provide to their host.

**CONCLUSION**

The phyllosphere is a complex and challenging environment to study microbiology. However, as molecular methods improve and our understanding of microbial genomics advances, we become better equipped to understand how the diversity of individuals contributes to the population ecology of the overall community. It will be intriguing to resolve what specific traits are needed for survival in the phyllosphere; already, we are developing our knowledge of the mode of action of a number of phytopathogens. These data will be of immediate value in diagnosis and disease prevention, but hopefully they will help to drive the development of suitable and effective biocontrol agents.\(^{1,32}\)

Physiology of Crop Yield

Gustavo A. Slafer

Department of Crop and Forest Sciences, University of Lleida, Centre UdL-IRTA, Lleida, Spain

Abstract
Improving yield is generally a major criterion when designing strategies for both breeding and management of major grain crops. In this chapter, we discuss firstly the two main approaches to understand grain yield in major crops (illustrated with examples from wheat); i.e., dividing grain yield into simpler numerical components, and understanding it as the consequence of growth and partitioning. Then a more mechanistic approach, combining the main and more functional elements of both models is proposed, identifying a critical growth period. As yield per unit land area must be limited by the source, an additional model is offered indicating when source-strength may actually regulate yield most strongly in agreement with the mechanistic model.

INTRODUCTION
Crop yield is normally the attribute which breeding programs and management decisions are mainly focused on. In the case of grain crops, it is the final outcome of crop growth and development processes, and is strongly regulated by genetic factors, environmental conditions, and genetic and environmental interactions throughout a growing season. A major aim of most crop physiologists is to identify processes that determine differences in yield because of genetic and environmental factors. In this article we have briefly reviewed the state of the art in this field, illustrating the case of wheat, one of the major crops whose yield physiology has been most comprehensively studied.

TRADITIONAL APPROACHES TO YIELD PHYSIOLOGY IN GRAIN CROPS
Yield is the proportion of the total biomass of the crop allocated to the harvestable organs. In the case of cereals and other grain crops, it is biomass allocated to grains. Traditionally it has been analyzed with two different, complementary approaches: the analysis of yield components and the analysis of dry matter accumulation and partitioning (Fig. 1).

Yield Components
The yield component approach has been the most popularly used one: It is simple and relatively easy. In this approach, yield is simply dissected into single numerical components (i.e., plants per unit land area, spikes per plant, spikelets per spike, grains per spikelet, resulting in the number of grains per m², and average individual grain weight; right part of Fig. 1). The approach has, however, a major drawback in that the components are not independent; in fact, they are consistently negatively related among themselves. The negative relationships between the subcomponents of the number of grains per unit land area could be attributed to feedback processes.[1] In the case of the two major yield components, the number of grains per unit land area and their averaged individual weight at harvest, whose generation is only minimally overlapped in time, the negative relationship may not be because of feedback processes. In fact, and regardless of what is often assumed, the negative relationship between the number and average weight of wheat grains seems to be largely independent of a strong competition for assimilates.[2] The lack of a strong (or any) competition among grains during their active growth, after the number of grains has been fixed, indicates that in most conditions the wheat canopy during postanthesis can provide assimilates in excess to the demands of the growing grains.[3,4] However, even recognizing a physiologically sound relationship between yield and grain number per m², based on the fact that wheat grains hardly compete for assimilates during their active growth, it is a small step toward understanding yield physiology: grain number per unit land area is as complex as, and harder to assess than, yield itself.
Dry Matter Accumulation and Partitioning

The approach based on dry matter accumulation and partitioning is far more mechanistic (Fig. 1, left panel). Understanding the determination of biomass requires crop assessment analyses and interpretations made at different times during the growing season. However, the approach is still quite straightforward: The only source of energy for crop growth is solar radiation and, therefore, the amount of accumulated growth depends proportionally on the amount of accumulated intercepted radiation, transformed into dry matter with certain efficiency (in the case of wheat and other C₃ cereals, in general between 1.0 and 1.5 g/MJ, or approximately twice those values if referring to photosynthetically active radiation; e.g., Ref.[5]). The main organs in charge of intercepting (and absorbing) solar radiation are leaves, and the main property of the leaves related to crop radiation interception is the area. Then leaf area index (LAI) (area of leaves per unit land area) is considered the main attribute of the crop canopy responsible for intercepting incoming radiation and in turn providing resources for crop growth and biomass accumulation. The capacity of a certain LAI to intercept incoming radiation depends on the properties of the leaves in the canopy. It is mathematically described as the light attenuation coefficient, and the higher the proportion of solar radiation absorbed by each unit of LAI (e.g., more planophile canopies) the higher the light attenuation coefficient of the canopy.[6] Although more mechanistically explaining yield than yield components, this approach has also a drawback: It assumes that increasing radiation interception and biomass accumulation would result in increasing yield irrespective of when the increased biomass was achieved. In other words, it assumes that yield is equally sensitive to changes in biomass at any time during crop growth. Although, perhaps, logical, this assumption does not fit the reality. For instance, experiments showing responses of yield to nitrogen fertilization disregarding whether the fertilizer was applied before sowing, in very early developmental stages or during late tillering,[7] demonstrate that yield is not only sensitive to changes in biomass accumulation but also when growth takes place. Another example may be provided by the fact that the optimum plant density for maximizing grain yield is far lower than that required for maximizing vegetative growth.[8]

**WHAT IS ACTUALLY CRITICAL FOR DETERMINING CROP YIELD?**

**Defining What Stages Are Critical**

From the pioneering work by Fischer,[9] it was clearly established, mainly from experiments in which wheat...
plants were subjected to brief but intense shading periods at different timings, that wheat yield is far more sensitive to changes in growth during the relatively short period from approximately 3 weeks before to a few days after anthesis than during any other timing (provided the crop has been adequately established soon after sowing). This relatively short “window” of phenological time coincides with the timing when the stems and spikes are competitively growing. Then final crop yield seems to be particularly sensitive to changes in resource accumulation and allocation in that period, determining the spike dry matter of the spikes per unit land area at anthesis.

Precisely, the number of grains per m², whose subcomponents in the “yield component approach” are being produced throughout the whole period from sowing to anthesis, seems to be virtually exclusively sensitive to growth and partitioning during the “window” of phenological time when stems and spikes grow actively. The result is the universal positive relationship between the number of grains per m² that the crop has at maturity and the dry mater per m² allocated into spikes at around anthesis. The word “universal” is used herein to express that only exceptionally this relationship has not been highly significant. For instance, disregarding where, in which conditions and with what cultivars the classic shading experiments were made, the relationship has always being confirmed. In addition, when less artificial treatments were applied (e.g., comparing yield physiology between high-yielding modern cultivars and their low-yielding predecessors; or between nitrogen-deficient crops and those well fertilized, between untreated controls and plots subjected to extended photoperiods reducing the length of the stem elongation phase, and so on) the relationship always explained much of the physiological bases of yield.

A Modified Model Recognizing a Critical Phase

Redefining the two most well known, general models to make them fit the empirical evidence, a new physiological model may be revealed. This model would accept that grain number is a major driving for yield in a crop in which final grain weight is largely independent of availability of resources during the effective period of grain growth. This does not mean at all that individual grain weight is invariable, but that genetic–environmental factors altering grain weight are largely direct effects on the capacity of the grains to grow rather than a resource-mediated process during the effective grain filling. As the subcomponents of grain number per m² cannot be used reliably to understand it physiologically, the mechanistic bases of grain number have to be found with a resource accumulation and allocation model. Using such a model requires focusing on growth/partitioning during the window of phenological time when yield has been found to be most responsive to...
environmental changes: in the case of wheat the stem elongation phase (Fig. 2). In this model, yield is maximized if LAI reaches its critical value by the onset of stem elongation, and both crop growth rate and partitioning to the growing spikes between stem elongation and anthesis are maximal. Both factors contribute to a large spike dry weight per m² at anthesis, largely determining the grain number per m² that a posteriori will be filled.

When Does Source Strength Drive Yield?

The model illustrated in Fig. 2 implies that although crop yield per unit land area is essentially a source-driven process, it is only during a rather short “window” of phenological time (say from 3 to 4 weeks before to 5 to 10 days after anthesis) that the crop sensitivity to source strength is critical for yield (Fig. 3). This window of time coincides with the timing when a very large number of potential sites that could produce a grain (tillers that might bear a spike, and floret primordia that might develop to a fertile floret and then fertilize to produce a grain) drops dramatically. The level will be determined by the particular genotype and environmental conditions, as reflected by the spike dry weight at anthesis, which in turn depends on the total crop growth during stem elongation and the partitioning of that growth between the stems and the spikes. To further increase the number of grains per m², which is critical for increasing productivity in a crop whose final yield is largely sink limited during the grain growth period, breeding and management must then be focused to further enlarge the spike dry weight per unit land area at anthesis, by either improving resource use, resource use efficiency, and/or partitioning toward reproductive growth during this particular window of phenological time.

CONCLUSIONS

Physiological analysis of yield determination in wheat suggests that the crop only responds significantly to changes in resource use and partitioning during a brief period of few weeks before to a few days after anthesis, when the number of grains largely determining yield (in a crop sink limited during grain growth) is established. The final number of grains is determined in relation to the dry weight per m² that the spikes reach at anthesis, which itself is a function of total crop growth during the stem elongation phase and the proportion of that biomass allocated into reproductive growth. For the sake of brevity, we have confined the analysis to wheat. However, with minor differences, the same kind of analysis fits well to other major grain crops.11

REFERENCES

Yield must be source limited by definition, as the “unit land area” (m² in an experimental plot and acre or hectare in real production) essentially represents a certain availability of resources in that area for a particular site × year × agronomic condition (the more the resources that can be used the higher the yield of the crop).
Physiology of Herbivorous Insects

Cedric Gillott
University of Saskatchewan, Saskatoon, Canada

INTRODUCTION

The long duration of insect–plant coevolution, especially the coevolution of insects and angiosperms since the Cretaceous (150 million years b.p.), has been a major contributor to the diversity of species seen in modern Insecta. Of the approximately 1 million extant insect species identified, more than 80% feed on plant material at some stage in their life. This high proportion, plus the enormous numbers of individuals in populations of a species that occur under appropriate conditions (e.g., up to $10^{10}$ locusts in a swarm), means that herbivorous insects play a major role in the flow of energy from primary producers to upper-level consumers. All parts of a plant may be used as food: leaves, stems, roots, sap, pollen, nectar, seeds, fruits, and nuts. In many species, but especially Lepidoptera and many Diptera and Hymenoptera, the diet may change from the juvenile to the adult stage. Further, insects may live on or within plants, some species (e.g., gall formers) triggering changes in the structure and physiology of the host for their benefit. To take advantage of the availability of plants as sources of food and shelter, an insect’s structure and physiology, especially in respect to feeding and reproduction, have taken on special adaptations.

EXTERNAL FEATURES

Body Form

In most adult insects and juvenile exopterygotes (insects with external wing development, such as grasshoppers, termites, true bugs, and thrips), the division of the body into three major regions (head, thorax, and abdomen) is readily visible (Fig. 1A). However, in many juvenile endopterygotes (insects with a pupal stage, such as ants, bees and wasps, beetles, butterflies and moths, and true flies), the separation of the regions may be indistinct (Fig. 1B, C). Each region comprises a number of segments, each of which primordially possessed a pair of appendages. In modern insects, these appendages may have disappeared; further, new nonsegmental structures may have arisen.

Head

The head is the major sensory center, typically bearing a pair of segmentation antennae, which are the principal location of sense organs for touch, taste, and smell, and nonsegmental eyes. Adult insects and juvenile exopterygotes have paired compound eyes, typically having several thousand photosensitive units. Compound eyes are capable of limited form perception, color vision, and in some species, for example the honeybee, perception of polarized light that can be used in navigation and orientation. Simple eyes (up to six pairs) found in juvenile endopterygotes and many adult insects each comprise fewer photosensitive units than compound eyes. In caterpillars and beetle larvae they appear to function like compound eyes. In adults they may measure light intensity, be involved in maintenance of diurnal rhythms, and help to maintain stability during horizontal flight. The mouthparts are derived from ancestral segmental appendages. In herbivorous insects they may be adapted for chewing (as in grasshoppers and beetles), piercing and sucking (aphids), or sucking only (butterflies and moths). In chewing mouthparts the well-developed mandibles typically have both cutting and grinding surfaces (Fig. 2A), while the labrum (upper lip), labium (lower lip), and maxillae taste and manipulate the food. In sucking species, the mandibles and maxillae generally form elongate styles that pierce tissue. The maxillae are interlocked to form the salivary and food canals, and the labium is developed as a protective tube (Fig. 2B).

Thorax

The thorax is the locomotory center of the insect. Typically, it bears three pairs of legs and, in adults only, the wings (Fig. 1A). Legs are secondarily absent in larvae of Diptera (Fig. 1C) and many Coleoptera and Hymenoptera. Though normally used for walking and running, legs may be modified for other functions, such as jumping (Fig. 1A), sound production, digging (Fig. 3A), and pollen collection (Fig. 3B). The legs of many insects, notably Diptera and Lepidoptera, have many chemosensilla as well allowing these insects to taste the substrate as they walk over it!
The evolution of wings and flight was a key factor in the success of insects. In the short term, flight facilitates escape from predators as well as dispersal, which is especially useful for species whose food sources and breeding sites are sparsely distributed. In the long term, dispersal leads to colonization of new habitats, geographic isolation, and, ultimately, speciation. Wings, generally two pairs, may be modified for both flight-related and other functions. Reduction to a single pair, or linking of the fore- and hindwings on each side, improves aerodynamic efficiency. In Diptera the greatly reduced hindwings (halteres) function as gyroscopic organs. The hardened forewings (elytra) of beetles provide protection. In crickets and grasshoppers the forewings are used in sound production. In Lepidoptera the wings may be colored and patterned for camouflage or to warn would-be predators that the insect is toxic. Occasionally, a nontoxic species (e.g., the viceroy butterfly) avoids being eaten by having wings that mimic those of a toxic species (e.g., the monarch butterfly).

**Abdomen**

The abdomen is the metabolic and reproductive center of the insect. The ancestral segmental appendages are lost on most segments, but at the posterior tip they remain as the external genitalia. In males they serve as clasping and intromittent organs, while in females they typically form the ovipositor whose structure reflects the site of egg laying. Thus, in grasshoppers that lay eggs in soil, the short and heavy ovipositor is used to dig a hole; in cicadas it is a hard tubelike structure that places the eggs in plant tissues; and in many Hymenoptera it is variously modified for sawing, piercing, boring, and stinging.

**Integument**

Covering the entire surface of the insect’s body—including the sense organs—as well as lining the foregut, hindgut, tracheal system, and parts of the reproductive system, is an inert, acellular layer called the cuticle. The cuticle may comprise, from inside to outside, the procuticle and a very thin, multilayered epicuticle. Where strength and rigidity are required, as for muscle attachment and general protection, the procuticle may be relatively thick. However, in regions of the body where flexibility or sensitivity is paramount, as at leg joints and over sense organs, only epicuticle is found. The outer layer of the epicuticle is a monolayer of wax molecules which, by reducing water loss from the body, has been another factor contributing to the success of insects as terrestrial organisms. The wax may also be important in preventing entry of microorganisms and in chemical communication where it serves as a pheromone or kairomone (see “Coordinating Systems,” following). Color production is also a function of the cuticle. Pigmentary colors result from the occurrence of specific pigments in the cuticle, including carotenoids, pteridines, and ommochrome. Iridescent colors result from the scattering of light due to the laminated nature of the procuticle.

**PHYSIOLOGY**

**Maintenance Systems**

Several insect maintenance systems differ markedly from those of vertebrates. For example, the gas-exchange system of insects comprises a tubular air-filled system with segmental openings to the exterior (spiracles) along each side of the body (Figs. 1A, 4). The tubes (tracheae and tracheoles) carry oxygen to and carbon dioxide from the core of tissues, making gas exchange highly efficient. Thus, the blood of insects has no role in gas exchange. Blood in insects does not travel within vessels as in vertebrates. Instead, the simple tubular heart, aided by various undulating membranes, pushes blood sluggishly past the internal organs and through the appendages. Excretion and salt–water balance are achieved via a series of fine Malpighian tubules (Fig. 5A) that filter ions, small organic molecules (including uric acid, the normal form of
In the grasshopper the mandibles have both shearing and grinding surfaces. The maxillae, labrum (upper lip), and labium (lower lip) are used to test the texture and taste of the food, as well as to manipulate it. In Homoptera the labium serves as a protective sheath for the delicate stylets, which are highly modified mandibles and maxillae. The maxillae interlock to form the salivary and food canals. (Fig. 2A in part redrawn from Pfadt, R.E. Field Guide to the Common Western Grasshoppers; USDA APHIS, Wyoming Agriculture Experiment Station, Bulletin 912, 1988. Fig. 2B in part redrawn from Dixon, A.F.G. Biology of Aphids; Edward Arnold, London, 1973. Reproduced by permission of HodderArnold Publishers.)

**Fig. 2**  Head and mouthparts: (A) Grasshopper (cutting and grinding mouthparts); (B) homopteran (piercing and sucking mouthparts). Nitrogenous waste), and water from the blood and release these into the hindgut. In the hindgut, resorption of useful materials occurs, and the remaining materials form urine.

**Coordinating Systems**

Like vertebrates, insects coordinate physiological activity by means of nervous and endocrine systems. The nervous system is relatively simple in both structure and function; much activity is the result of simple reflex pathways, and insects possess very limited ability to learn and memorize. By contrast, insect hormonal systems have roles comparable to those of vertebrates—for example, in reproduction, growth, excretion, and blood–sugar regulation—and appear to be equally complex. Communication and coordination of behavior among insects may include visual, tactile, and auditory stimuli, but chemical signals are usually of greater importance. They include pheromones, allomones, and kairomones, which are chemicals released from the body of one insect to induce a behavioral or physiological response in other insects. Pheromones act intraspecifically and are used by numerous species, but especially Lepidoptera and Coleoptera, to attract mates. Indeed, synthetic sex attractants are widely used in integrated pest management (IPM). Other pheromones regulate sexual maturation and caste differentiation in social insects; mark trails to and from food and indicate its quality and quantity; stimulate aggregation or
dispersion; and warn of impending danger. Allomones are used to repel would-be predators, as in the release of formic acid by some ants. Kairomones are chemical signals (including some pheromones) released by one species and detected by another. For example, the aggregation pheromone of bark beetles is used by hymenopteran parasites to locate their hosts!

Food Acquisition and Utilization

The feeding habits of herbivorous insects have special significance for humans from an opposite perspective. Some insects cause enormous damage to crops and stored plant products, whereas others are of massive benefit as pollinators. Generally, olfactory stimuli trigger the initial orientation to a potential food source. Phagostimulants or deterrents on or within the food then determine whether feeding continues. The alimentary canal comprises three regions: foregut, midgut, and hindgut (Fig. 5A). In insects that feed on solid matter, the canal is generally fairly short. By contrast, in most sap feeders, which must both...
concentrate the food prior to digestion and prevent the excess water from diluting the blood, the canal is long and coiled back upon itself, and it passes through a filter chamber (Fig. 5B). Here, the anterior midgut and hindgut are closely adjacent, allowing water to pass from the former to the latter and thus to be excreted without entering the body cavity. Generally, the foregut is where food is stored. The midgut, lined with a peritrophic matrix that protects this region from physical damage and entry of microorganisms, is where digestion and absorption occur. The hindgut processes undigested material into feces, though in many herbivores, especially those that feed on woody materials, this region may have special sections that house symbiotic bacteria or protozoa to facilitate digestion. Only a few insects manufacture enzymes capable of splitting cellulose and hemicellulose. The hindgut symbionts degrade such compounds into glucose and organic acids, which are then absorbed through the hindgut wall.

Following their absorption across the gut wall, products of digestion are metabolized in the fat body, a tissue analogous in function to the vertebrate liver. Here, they are converted into appropriate energy-supplying or growth-promoting molecules, or are stored. The fat body is also the principal site for detoxification of insecticides and plant-produced toxins.

Reproduction

Generally, insects have a high reproductive capacity and a short generation time. By facilitating rapid adaptation to changing environmental conditions, including development of insecticide resistance, these factors have also been important in the success of insects. Most insects reproduce sexually and lay eggs. Males locate females using visual, auditory, or chemical cues, especially sex attractants. The latter may be active over distances of several kilometers. Among herbivorous insects, gravid females determine which are suitable host plants by chemical or visual cues. Eggs may be laid in soil, or on or within plant tissues. Embryogenesis, larval development, and metamorphosis are usually rapid, enabling several generations to occur each year. However, in cold climates there may be only one generation annually, with most species overwintering in the egg or pupal stage.

Though most species are bisexual and lay eggs, others—including many pestiferous Homoptera—including parthenogenesis (which produces female-only generations) and sometimes also viviparity in their reproductive repertoire. These unusual strategies lead to massive population increases, hence the insects’ ability to exploit a temporary abundance in their food supply and their prominence as major vectors of plant diseases.

INTRODUCTION

Plants produce a wide variety of secondary metabolites that have evolved as defense compounds against herbivores and microbes. Some secondary metabolites attract pollinating insects or fruit-dispersing animals; others serve as UV protection or as signal compounds. Secondary metabolites can be divided into two main groups—those without nitrogen and those with nitrogen in their structures. Nitrogen-containing compounds include alkaloids, amines, nonprotein amino acids, cyanogenic glycosides, glucosinolates, protease inhibitors, and lectins. Nitrogen-free compounds are various terpenoids (mono-, sesqui-, di-, tri-, and tetraterpenes; saponines; and cardiac glycosides), polyketides (anthraquinones), phenolics (flavonoids, anthocyanins, galloyl and catechol tannins, phenolic acids, lignans, and lignins), and polyacetylenes. The modes of action of these compounds are briefly discussed.

WHAT ARE SECONDARY METABOLITES?

A chemical analysis of low molecular-weight substances present in a plant reveals the usual inorganic ions, amino acids, sugars, organic acids, fatty acids, and some other compounds that are needed for primary metabolism or development. In addition, all higher plants produce one or several representatives of the so-called secondary metabolites (SMs), which are also low molecular-weight compounds. In contrast to primary metabolites, SMs are not essential for a plant in terms of primary metabolism; i.e., a plant can usually survive without a particular SM, especially when grown under protection in a greenhouse.[1–9]

SMs can have ecological functions in that they serve to protect against herbivores, microbes, or competing plants. Some SMs also function as signal compounds to attract pollinating or seed-dispersing animals. SMs usually occur in complex mixtures that also differ among plant organs and developmental stages; e.g., seeds have SM profiles that often differ from those of leaves and roots. In general, a particular group of plants produces two to three main types of SMs concomitantly, such as phenolics, terpenoids, or alkaloids. Often, a basic structure is present that is varied by several substitutions, such as additional OH-groups, methyl-groups, or double bonds. SMs are dynamic compounds showing turnover, and their biosynthesis can be enhanced upon attack by microbes or herbivores.[1,6–9] Jasmonic and salicylic acid are important signal molecules in this context.[10]

Some SMs occur in phylogenetically related taxa (e.g., glucosinolates in families of the Capparales), whereas others have a broader distribution (often a major radiation in a particular tribe or family and outliers in several others). Considering the whole plant kingdom (including algae, mosses, horsetails, and ferns), an impressive diversity of SMs exists. Fig. 1 gives an estimate of the numbers of known secondary metabolites and illustrates a few representative structures. Three major groups of SMs can be recognized: nitrogen-containing substances, terpenes, and phenolics.

PHYTOCHEMICAL DIVERSITY

Nitrogen-Containing Secondary Metabolites

Over 14,000 nitrogen-containing SMs have been described so far: Alkaloids, amines, nonprotein amino acids, cyanogenic glycosides, and glucosinolates are the main compounds in this group. A few SMs of high molecular weight should also be considered in this context: Some plants accumulate peptides and proteins (protease inhibitors, amylase inhibitors) that play a role in antimicrobial and antitherbivore defense. Their biosynthesis can be induced upon wounding or microbial attack.

Nonprotein amino acids (NPAA)

In addition to the 20 common L-amino acids, more than 400 other amino acids that are not building blocks of proteins exist in plants.[1–5] NPAs often figure as antimetabolites or protein amino acids and can be considered to be their structural analogues. For example, 3-cyanoalanine is an analogue to L-alanine, S-aminoethylcysteine to L-lysine, L-azetidine-2-carboxylic acid to L-proline, and L-canavanine or
L-indospicine to L-arginine. Because NPAAs are often (at least partly) remobilized during germination, they function as N-storage compounds in addition to performing their role as defense chemicals.

Amines

Aliphatic mono- and diamines, polyamines, aromatic amines, and amine conjugates are the main SMs in this group. Aliphatic monoamines and diamines are widely distributed SMs in plants, and occur as independent products in their own right or as intermediates in the biosynthesis of alkaloids (as precursors for several groups of alkaloids, such as pyrrolizidine, nicotine, tropane, quinolizidine, Lycopodium, and Sedum alkaloids). Simple amines serve as attractants in some flowers (e.g., Arum maculatum) or as defense compounds in many other plants. Aromatic amines derive from tryptamine and tyramine. Because several tryptamine and tyramine derivatives are structurally identical or similar to those of the neurotransmitters serotonin, dopamine, or noradrenaline they may interfere with the corresponding receptors. Hallucinogenic or stimulating effects have been reported for bufotenine, psilocybin, psilocin, N,N-dimethyltryptamine, mescaline, ephedrine, or ergot alkaloids.

Cyanogenic glycosides

Cyanogens are derivatives of 2-hydroxynitriles that form glucosides with β-d-glucose. More than 60 different cyanogenic glycosides have been described from 2600 plants (mainly Rosaceae, Fabaceae, Gramineae, and Araceae). When plants are wounded by herbivores or other organisms, the cellular compartmentation breaks down and cyanogenic glycosides are hydrolyzed by β-glucosidase and nitrilase to the corresponding aldehyde

Fig. 1 A number of known secondary metabolites.
or ketone and hydroprussic acid (HCN). \[^{[15]}\] HCN is highly toxic for animals or microorganisms because it inhibits electron transfer components of the respiratory chain and binds to other enzymes with metal ions. Foods that contain cyanogens, such as manihot (\textit{Cassava esculenta}) and sorghum, have repeatedly caused intoxication and even death in humans and animals.

**Glucosinolates**

Glucosinolates contain sulfur as an additional element (thioglucoisides). When hydrolyzed, glucosinolates liberate D-glucose, sulfate, and an unstable aglycone, which normally converts to isothiocyanate (common name, mustard oil) as the main product. \[^{[2–9,15]}\] Isothiocyanates are responsible for the distinctive, pungent flavor and odor of mustards and horseradish. More than 80 different glucosinolates have been found in the Capparales (families Capparidaceae, Brassicaceae, Resedaceae, Moringaceae, and Tropaeolaceae).

**Alkaloids**

Alkaloids represent a large and diverse class of SMs with a heterocyclic nitrogen that can react as a base. \[^{[1–9,11–16]}\] Alkaloids have been detected in about 15% of plants, bacteria, fungi, and even animals. Within the plant kingdom, they occur in primitive groups such as \textit{Lycopodium} or \textit{Equisetum}, in gymnosperms, and most abundantly in angiosperms. Alkaloids often exhibit toxicity toward animals and humans. Their main targets are elements of the neuronal signal transduction system. \[^{[13,14]}\] Alkaloids certainly evolved as defense chemicals against herbivores, but also inhibit microorganisms and other plants. In addition, some plants employ them as degradable N-transport and N-storage compounds. \[^{[5]}\]

**Secondary Metabolites Without Nitrogen**

Over 20,000 nitrogen-free SMs have been described so far. Terpenoids, phenylpropanoids, flavonoids, polyketides, and polycyctenes, are the main compounds in this group. \[^{[1–9]}\]

**Terpenoids**

Main terpenoids include monoterpenes (with 10 C atoms), sesquiterpenes (15 C), diterpenes (20 C), triterpenes (30 C), steroids (27 C), tetraterpenes (40 C), and polyterpenes. Although their main building blocks are simple, most terpenes represent complex structures because of various substituents and secondary ring formations. \[^{[1–9]}\]

Mono- and sesquiterpenes are often volatile and can be isolated as essential oils. These compounds are usually lipophilic and are stored in specialized oil cells, trichomes, resin channels, or other dead cells. \[^{[15]}\] They are especially abundant in Asteraceae, Apiaceae, Lamiaceae, Rutaceae, Lauraceae, Cupressaceae, Pinaceae, Myrtaceae, and Zingiberaceae. An intriguing number of complex ring structures can be found in sesquiterpenes. Some of them are highly reactive compounds, such as ptaquiloside in the fern (bracken) \textit{Pteridium aquilinum} or the sesquiterpene lactone helenalene of \textit{Arnica} species, which can alkylate DNA and proteins. Bracken is known to cause bladder cancer in humans and livestock. Some sesquiterpenes from gymnosperms mimic the insect juvenile growth hormone (a terpenoid with 17 or 18 C). In general, mono- and sesquiterpenes function as chemical defense compounds against herbivores and microbes, but the volatile terpenes also serve to attract pollinating insects.

Among diterpenes we find extremely complex ring structures, some of which, such as phorbol esters of Euphorbiaceae and Thymelaeaceae, are infamous for their toxicity (they activate protein kinase C and can act as tumor promoters). The plant hormone gibberellic acid belongs to the class of diterpenes, as does forskolin, a potent activator of adenyln cyclase. Another diterpene, taxol A (paclitaxel, taxol), can be isolated from several yew species and has been used for almost 10 years with great success in the chemotherapy of various tumors. \[^{[7,13,14]}\]

Triterpenes and steroids can occur as aglycons but more often occur as saponins. Whereas free triterpenes and steroids are lipophilic compounds, the saponins are water soluble and amphiphilic molecules that can make biomembranes leaky. They therefore show characteristics of broad antimicrobial and antiherbivore activity. Saponins are widely distributed in the plant kingdom; approximately 70% of all plants produce them. A special case of steroidal saponins is cardiac glycosides that inhibit Na\(^+\),K\(^+\)-ATPase and are therefore strong toxins (but are useful in heart medication). Cardiac glycosides can be divided into two classes: cardenolides and bufadienolides. \[^{[1–9]}\] Another class of bioactive steroids is the phytoecdysones, which have been isolated from ferns and several higher plants. They mimic the insect moulting hormone ecdysone and are therefore insecticidal.

Carotinoids represent the most important members of tetraterpenes. Carotinoids are the precursors for vitamin A in animals, used to produce retinal and retinoic acid (retinoids bind to nuclear receptors and are local mediators of vertebrate development).

Polyterpenes, consisting of 100 to 10,000 isoprene units, are prominent in latex of Euphorbiaceae and other families; they are used commercially in rubber (from \textit{Hevea brasiliensis}) or gutta-percha.
Phenolic compounds: Phenylpropanoids, coumarins, flavonoids and tannins

Phenylpropanoids can occur as simple compounds (as phenylacrylic acids, aldehydes, or alcohols) that differ by their degree of hydroxylation and methoxylation. Phenylpropanoids can also be conjugated with a second phenylpropanoid, such as rosmarinic acid (an abundant tannin of Lamiaceae) or with amines, such as coumaroylputrescine.\(^{[1–9]}\)

Coumarins and furocoumarins are common in certain genera of the Apiaceae, Fabaceae, and Rutaceae. Furocoumarins with a third furane ring form linear psoralen or angular angelicin types. Furocoumarins can intercalate DNA, and upon illumination with UV light can form cross-links with DNA bases and also with proteins.\(^{[7]}\) They are therefore mutagenic and possibly carcinogenic. In plants they serve as defense compounds against herbivores and pathogens.

Phenylpropanoids can condense with a polyketide moiety to flavonoids, chalcones, catechins, and anthocya-nins. These compounds are characterized by two aromatic rings that carry several phenolic hydroxy, methoxy, and sugar groups. Many of the flavonoids, chalcones, and anthocyanins are widely distributed in higher plants and show colors under visual and UV light and are typical SMs of flowers and fruits. The color of anthocyanins depends on the degree of glycosylation, hydrogen ion concentration, and the presence of certain metals (e.g., aluminium ions) in the vacuole. These SMs function to attract pollinating insects or fruit-dispersing animals. The phenolic hydroxyl groups can interact with proteins to form hydrogen and ionic bonds and can therefore interfere with a multitude of molecular targets.

Isoflavones are common SMs in legumes. They exhibit estrogenic properties and inhibit tyrosine kinases. Therefore, they are often regarded as useful compounds that might play a role in the prevention of certain cancers. Such ingredients are called nutraceuticals (in analogy to phytopharmaceuticals). Other isoflavones, such as rotenone, have potent insecticidal properties and have been used as biorational pesticides for plant protection.

Catechins, which often dimerize or even polymerize to procyanidins and oligomeric procyanidins, form a special class of phenolics. These nonhydrolyzable tannins are characterized by a large number of hydroxyl groups that can interact with proteins to form hydrogen, ionic, and possibly even covalent bonds. These compounds serve as defense chemicals against invading pathogens and herbivores. Another important group of tannins comprises esters of gallic acid with sugars. These hydrolyzable gallotannins are widely distributed in plants, often in bark, leaves, fruits, and galls. Gallotannins contain a large number of phenolic hydroxyl groups, so can form stable protein-tannin complexes and thus interact with a wide variety of protein targets in microbes and animals.\(^{[1,5,7]}\)

**Polyketides**

Important polyketides are anthraquinones, quinones, and flavonoids. SMs with an anthracene skeleton can be present as anthrones, anthraquinones, anthranols, dianthrones, naphthodianthrones, dianthranoles, and corresponding mono- or diglycosides.\(^{[1–9]}\) Anthraene derivatives are common in certain genera of the Polygonaceae, Rhamna-ceae, Fabaceae, Rubiaceae, Hypericaceae, and Aloes.

Glycosylated monomeric anthrones exhibit a strong laxative activity in vertebrates and can be regarded as potent defense chemicals. They have also been used in medicine as laxatives for several thousand years.

**Carbohydrates**

Several carbohydrates (such as glucose, galactose, or fructose) form glycosides with SMs and are thus participants in both primary and secondary metabolism.\(^{[1–9]}\) Other carbohydrates appear to be allelochemicals in their own right: An example is phytic acid (a myoinositol esterified with up to six phosphate groups) that can complex Ca\(^{++}\) and Mg\(^{++}\) ions and thus functions as an antinutritive substance. Several di-, tri-, and oligosacchar-ides—such as stachyose and raffinose, typically found in seeds and roots—produce substantial flatulence in herbivores and thus come closer to typical SMs in being regarded as defense compounds against herbivores.

**CONCLUSION**

SMs show an impressive structural diversity that can be understood from an ecological and evolutionary perspective. Many SMs have evolved as bioactive compounds that interfere with nucleic acids or proteins (known as evolutionary molecular modelling) and show antimicrobial or insecticidal and pharmacological properties. SMs are therefore of interest in medicine as therapeutics and in agriculture as biorational pesticides. Several SMs have antioxidative, radical scavenging, or estrogenic properties; food and crops containing these nutraceuticals will play an increasingly important role in nutrition.\(^{[6,7]}\)

Many crop and food plants originally produced SMs before domestication. During plant breeding, many of the traits leading to SMs have been eliminated because
corresponding SMs were toxic, bitter, or unpalatable.\[^{5}\]
Unfortunately, this strategy also removed the natural resistance of many cultivars with the consequence that human-made synthetic plant protectives must replace the natural defense compounds formerly present.

In light of the novel strategies of genetic engineering and food processing, SMs should not be regarded as useless compounds. On the contrary, SMs represent valuable traits that might be used to improve viability, resistance, and the nutritional quality of crop and food plants.

Phytochrome and Cryptochrome Functions in Crop Plants

Jim Weller
University of Tasmania, Hobart, Tasmania, Australia

INTRODUCTION

Light has profound effects on plant development. Variation in the quality and irradiance of light can influence processes throughout the plant life-cycle, including seed germination, stem elongation, leaf expansion, bud dormancy, synthesis of photosynthetic and photoprotective pigments, and the initiation of flowering. Light is perceived and its developmental effects mediated by two important families of photoreceptor proteins: the phytochromes, which predominantly absorb red (R) and far-red light (FR), and the cryptochromes, which primarily absorb blue light (B). Most recent progress in understanding the roles of these photoreceptors in plant development has come from studies in Arabidopsis thaliana, although phytochrome and cryptochrome functions are also being explored by a genetic approach in other model species including tomato, pea, and rice. In most cases, photoreceptor functions in these species have been found to be broadly consistent with their roles in Arabidopsis. However, the fact that these species differ in growth habit, physiology, and photoreceptor complement means that they offer a broader perspective on photoreceptor function and how genes controlling photoreceptor function might be useful for modifying specific traits in a diverse range of crop plants.

PHOTORECEPTOR GENE FAMILIES

The phytochrome and cryptochrome photoreceptors are encoded by small gene families in most species so far examined. The full extent of these gene families is known in only a few species, but even so it is clear that they can be somewhat variable in size. For example, different lineages within the phytochrome and cryptochrome families may have undergone independent duplications. The best illustration of this is the existence of phyB-type gene pairs in Arabidopsis (phyB and phyD) and tomato (phyB1 and phyB2), where members of each pair are more closely related to each other than to either of the corresponding genes from the other species.[1] There is also evidence for recent duplications within the cryptochrome gene family. Whereas Arabidopsis has only two cryptochromes (cry1 and cry2), both tomato and barley have three expressed CRY genes, including two CRY1-like genes.[2] It is likely that as more species are examined more such instances will be identified. A substantial difference in phytochrome gene complement is also seen in monocots. In contrast to the five found in Arabidopsis, rice and sorghum have only three phytochromes, corresponding to phyA, phyB, and phyC lineages, suggesting that monocots may not have undergone the expansion within the phyB lineage that is seen in dicots.

Despite the differences in photoreceptor gene complement, the basic features of specific photoreceptors seem to be generally conserved. For example, where examined, phyB-type phytochromes have generally been found to be relatively stable, whereas phytochrome A is degraded in the light and PHYA expression is strongly down-regulated.

STUDYING BASIC PHOTORECEPTOR FUNCTIONS IN CROP PLANTS

Photoreceptor functions in a wide range of crop species have been studied for many years by means of indirect physiological approaches involving irradiation with monochromatic light. However, direct information about photoreceptor functions relies on the use of mutants or transgenic lines with altered photoreceptor levels. Table 1 lists the photoreceptor mutants that have been isolated in Arabidopsis and a range of other higher plant species. In general, far less is presently known about cryptochrome function than about phytochrome function, and whereas many phytochrome-deficient mutants are known in crop species, the only known cryptochrome mutant is the cry1 mutant of tomato.

De-etiolation

As germinating seedlings emerge from the soil, or after dark-grown seedlings are transferred to white light, they display a developmental response called de-etiolation, which includes the co-ordinated inhibition of hypocotyl/
epicotyl/coleoptile elongation, promotion of leaf expansion, and synthesis of chlorophyll and anthocyanin. The basic features of photoreceptor function appear relatively well conserved between *Arabidopsis* and other species that have been examined to date. Analyses of photoreceptor mutants in tomato and pea have shown that phyA is the only receptor mediating de-etiolation responses to the light in the FR region of the spectrum. PhyA is present at high level in dark-grown seedlings and can mediate de-etiolation responses to low irradiance R and B. As a result it is important during the initial phase of the dark-to-light transition. Under high irradiances, the level and influence of phyA decline rapidly, and phyB and cry1 become the predominant photoreceptors, mediating responses to R and B, respectively.[3,4] A deficiency in either one of these photoreceptors enhances elongation growth and impairs leaf development. This may be quite dramatic (e.g., lh in cucumber, ein in *Brassica*) or relatively mild (e.g., phyB1 in tomato). The difference may have to do with the existence in some species of multiple phyB with overlapping functions.

In contrast, phyA deficiency has little overall effect on seedling morphology in pea, tomato, or rice grown under high irradiance white light, presumably because the effects of phyA are masked by phyB and cry1 under these conditions. However, in the absence of these photoreceptors or under low irradiances of light, a clear phenotype for phyA mutants does become evident. The relative contribution of phyA to de-etiolation also differs in different species. In tomato, phyA has a small role in R regardless of which other photoreceptors are present, but in pea, it plays a substantial role in the absence of phyB.[3,4] This may be related to differences in stability of the phyA protein. Also, phyA can interfere with phyB function, an interaction best illustrated in tomato, where phyA mutants show a phyB-dependent enhancement of anthocyanin synthesis under R and W.[5]

### Shade-Avoidance

Growth of fully de-etiolated plants is also significantly affected by light, in particular by the amount of light and the proportion of FR, in a syndrome termed the shade-avoidance response. In terms of photoreceptor function, the shade-avoidance response actually consists of two distinct photoresponses. PhyB-type phytochromes induce leaf expansion and inhibit stem elongation in response to R. FR activates phyA to induce a similar set of responses, but inactivates phyB phytochromes by converting them to their Pr form. Most phyB mutants thus show a partial shade-avoiding phenotype. Like the seedling response to R, strength of this phenotype varies with species, possibly depending on the number of phyB-like phytochromes present. For example, the phyA phyB1 phyB2 triple mutant of tomato shows a strong shade-avoidance response, whereas in pea, the phyA phyB double mutant is completely unresponsive.[4,5] The activity of phyA may also be an important factor determining the overall strength of the shade-avoidance response in any given species. For example, tomato has a strong shade-avoidance response that is not much influenced by the loss of phyA. In contrast, pea shows a weak shade-avoidance response that is dramatically enhanced in plants lacking phyA.[4,5] This interference of phyA with shade-avoidance has also been examined with a view to practical applications. Studies in several species have shown that elevated levels of phyA can enhance the response to the FR present in canopy shade, thus suppressing the shade-avoidance response and even causing proximity dependent dwarfing.[6]
Flowering and Photoperiodism

The tendency to flower early is often seen as part of the shade-avoidance syndrome. Consistent with the important role for phyB-type phytochromes in shade-avoidance responses, phyB-deficient plants in several species show early flowering. The early-flowering phenotype of phyB-deficient plants is seen under both long and short photoperiod conditions, and in both short-day plants (SDP; e.g., sorghum, rice) and long-day plants (LDP; e.g., Arabidopsis, pea). For this reason phyB is not thought to be involved with detection of daylength as such. Instead, the primary function of phyB-type phytochromes may be to detect noncompetitive conditions (high R:FR ratio) and delay flowering. As the FR content increases, these phytochromes are inactivated and plants flower early as a result. One exception is seen in Nicotiana plumbaginifolia, in which flowering is promoted by low R:FR, but is delayed in the phyB-deficient hig mutant. In tomato, phyB mutations have little effect on flowering, although it is not clear whether this is due to the compensating action of another phytochrome or the possibility that flowering is not responsive to R:FR in this species.

In contrast to phyB, a clear role for phyA has been identified only in LDP. In rice, the only SDP for which phyA mutants have been isolated, the loss of phyA does not have any discernable affect on flowering, suggesting that it may not be important for flowering or photoperiodic responses in SDP. In the LDP pea, phyA deficient mutants are late flowering in LD, and show pleiotropic characteristics of plants grown in SD. Delayed flowering is also seen in phyA mutants of Arabidopsis under some long day conditions. PhyA thus appears to have an important role in the promotion of flowering in response to day extensions, and thus acts antagonistically to phyB. Transgenic potato plants with reduced phyA levels failed to inhibit tuberization under long photoperiods whereas transgenic aspen overexpressing phyA failed to enter dormancy under short photoperiods. Taken together, these results suggest that the level of phyA may determine the critical day length for long-day responses and that phyA acts to promote the transition from growth strategies appropriate to winter (slow vegetative growth, production of vegetative storage organs, dormancy) to those appropriate for summer (rapid vegetative growth and induction of flowering).

Other Responses

There are many other documented responses to light in crop plants that have yet to be investigated from a genetic perspective. Phytochrome has a well known role in germination of many small-seeded species, and there is some limited genetic evidence for the role of phytochromes in tomato seed germination but pea and rice are large-seeded and show no substantial light effects on germination. There is also evidence from tomato that phytochrome regulates competence for shoot regeneration and specific aspects of fruit ripening. Apical dominance is another trait that is clearly modified by photoreceptor action. Activation of the shade-avoidance response results in greater elongation growth and reduced branching or tillering. In contrast, phyA in pea acts to suppress lateral branching, although this can be explained through its effects on the photoperiodic response. In addition, both phyA- and phyB-type phytochromes are likely to influence many other important traits and processes that are responsive to photoperiod, including root development, tuberization, fruit set and development, and partitioning of dry matter between stem and leaf.

CONCLUSION

It is clear that the phytochrome and cryptochrome photoreceptors affect several different responses of applied interest. Modification of photoreceptor activity, either through classical breeding or transgenic manipulation, may offer some prospects for improvement of specific light-responsive traits. A better understanding of light responses may help to modify seedling growth in dense propagation systems, through selection and development of light sources and transparent sheeting materials used in glasshouses and growth. Selection strategies including a consideration of shade-avoidance responses may lead to improved harvest index, increased growth of storage organs, and reduced lodging, features which may in turn allow higher cropping densities and more efficient harvesting. Conversely, in some fiber crops constitutive shade-avoidance may have desirable effects on fiber properties. Modification of photoreceptor activity may help to control photoperiod responsiveness, making it possible to accelerate, delay, or prevent flowering and bolting, and help in the development of crop varieties better suited to a given location or cropping regime. Fruit-specific regulation of photoreceptor activity may provide a means to modify fruit properties. There is no doubt that continuing to expand our knowledge of photoreceptor functions in a broader range of crop plants will offer further useful insights and applications.

Phytoremediation

Clayton L. Rugh
Michigan State University, East Lansing, Michigan, U.S.A.

INTRODUCTION

Phytoremediation is defined as the use of plants for degradation, removal, and detoxification of chemical pollutants from contaminated soils, sediments, or waters. Phytoremediation is considered a subcategory of bioremediation, or the use of biological organisms, processes, or products for environmental detoxification and typically implies microbes, such as bacteria and fungi. The term phytoremediation is formed from the Greek "phyton", for "plant" and the Latin "remedium" for "to heal again." Phytotechnologies have garnered increasing scientific and commercial interest as a more environmentally compatible and less expensive method of site remediation relative to engineering-based methods, such as excavation, soil washing, or soil incineration. Planted systems may provide numerous accessory functions in addition to contaminant removal such as pollutant containment via high-volume water use and erosion mitigation by soil and sediment stabilization against wind and rain. Important ecological benefits of phytoremediation include soil enrichment with root-released materials and decomposed plant litter, soil aeration, and micro- and macrofauna habitat development. Agricultural-scale costs of phytoremediation may be considerably less expensive than intensively engineered approaches. The reduced cost and ecologically restorative qualities of phytoremediation have advanced this technology as a viable and attractive option for environmental cleanup. The majority of phytoremediation laboratory research and field application has occurred with naturally occurring plants upon empirical discovery of their exceptional abilities for such applications. This has led to a growing body of scientific literature and wider acceptance for plants in many aspects of environmental rehabilitation. Further characterization of plant physiological, biochemical, and molecular genetic mechanisms in response to target contaminants is critical for optimization and advancement of the field of phytoremediation. Subsequently, biotechnological plant improvement is being pursued to enhance the utility of plants as an aggressive and effective method of environmental decontamination.

PHYTOREMEDIATION TECHNOLOGIES

Laboratory and greenhouse experimentation have given rise to phytoremediation treatment methodologies for a wide range of environmental contaminants, including heavy metals, petroleum and its manufacturing byproducts, solvents and degreasers; agricultural chemicals such as fertilizers, pesticides and herbicides, explosives, and radioisotopes. The general field of phytoremediation is subclassified into more specific areas of application, dependent upon the contaminant chemical class and treatment site conditions. Phytoextraction describes the use of metal-tolerant plants, or hyperaccumulators, to acquire elevated levels of inorganic contaminants in their aboveground tissues with subsequent harvest, recovery and disposal or recycling of the metals. Phytodegradation is the use of plants capable of enzymatic breakdown of organic, or carbon-containing, compounds to simpler and less toxic chemicals either alone or in combination with soil microbes, the latter process also known as phyto-stimulation or rhizosphere-assisted bioremediation. Phyto-stabilization refers to the use of plants to immobilize contaminants within the soil profile to minimize pollutant escape or biological exposure. Rhizofiltration describes the use of plant root systems to intercept or degrade waterborne contaminants.

Phytoextraction

The initial proposal for the use of plants as an applied technology for the treatment of polluted habitats grew out of the discovery of plants that could grow on metal-rich, nutrient poor soils and “hyperaccumulate” elevated levels of these otherwise toxic metals in their leaves and stems. In their native habitats, these metal hyperaccumulating plants had been utilized by local indigenous populations as indicators of useful metal deposits. Researchers proposed that these species could be used to revegetate mining- or smelter-impacted, barren soils with subsequent soil regeneration by plant extraction and harvest of the toxic metal pollutants. In addition to beneficial minerals, other plant species have been observed to accumulate elevated levels of nonnutrient,
hazardous elements such as thallium, cadmium, and arsenic. To accelerate the phytoextraction process, chemical amendments such as synthetic chelators, e.g., ethylene diaminetetraacetic acid (EDTA), or weak acids, e.g., citrate, have been used to enhance soil-pollutant desorption and plant uptake rates. Hyperaccumulating species are being intensively researched for better understanding of their physiological and biochemical mechanisms to allow optimization and genetic engineering of these novel processes in larger biomass, agronomically compatible crops.

Phytodegradation

Plants have been demonstrated to enzymatically degrade a variety of carbon-based, or organic, pollutants, including the degreaser solvent trichloroethylene (TCE) and explosive chemicals, such as trinitrotoluene (TNT).\(^\text{[3]}\) Phytodegradation of organic pollutants may occur by secretion of enzymes into the surrounding soil matrix or uptake and metabolism within root cells or in aerial plant tissues. Contaminant uptake may be limited to relatively hydrophilic chemicals, with an octanol–water partitioning coefficient (log \(K_{ow}\)) less than 3. In addition to breakdown of water-soluble pollutants, large biomass plants, particularly trees, can contain the contaminants within or extract them from the rhizosphere during periods of intensive water uptake and transpiration.

Phytostimulation

For most organic pollutant phytoremediation, soil microbes are expected to play a significant and possibly essential role for effective contaminant degradation. Phytostimulation describes the reciprocal benefits achieved for pollutant biodegradation in planted soils, where plant roots supply nutrients, enzymes, and aeration, and microbes, including fungi and bacteria, contribute enhanced soil colonization and complementary metabolic capabilities. Vegetated soils have been demonstrated to possess greater numbers of total bacteria and faster rates of pollution reduction than unplanted treatments.\(^\text{[3]}\) Microbial co-metabolism may be most critical for degradation of strongly hydrophobic pollutants that are not readily accumulated into plant roots, such as polychlorinated biphenyls (PCBs). In addition, bacterial species capable of biodegrading PCB were observed to be preferentially enriched in the rhizosphere of certain plant species.\(^\text{[4]}\) As observed for metal phytoremediation, plant species selection is important for effective phytostimulation of rhizosphere-mediated biodegradation of organic contaminants (Fig. 1).

Phytostabilization

This approach is the opposite of phytoextraction, in that vegetation is utilized primarily as a mechanism to immobilize heavy metal pollutants in the rooted soil profile. Phytostabilization may be suitable for situations where the primary hazard is wind or storm water discharge of the contaminants and engineering approaches such as excavation or solidification are considered excessively disruptive or impractical. Heavy metal contaminants can be effectively immobilized by combined use of metal tolerant, vegetated groundcover and soil amendments, such as organic composts or adsorptive minerals.\(^\text{[5]}\) Phytostabilization may be implemented as a temporary or long-term solution depending upon the level and type of contamination and site proximity to sensitive natural resources or populations. For long-term applications, it is effective to use perennial species that are acclimated to the site to avoid displacement of the essential plant community with subsequent site destabilization.

Rhizofiltration

This technology utilizes the highly reactive and extensive surface area of plant root systems when grown in aqueous
or hydroponics conditions. Rhizofiltration has been demonstrated as an effective approach to extract and concentrate a wide variety of metals, including lead, cadmium, and chromium, from wastewater streams. This method has been utilized as an effective treatment for both industrial waste effluents and field-scale constructed wetland applications.

LIMITS TO PHYTOREMEDIATION

Phytoremediation is restricted by the natural capabilities for plant growth and development, which include limited rooting depth, discontinuous growing season, and failure under extreme environmental conditions. In contrast, engineering-based technologies are capable of extracting pollutants from great subterranean depths, can operate year round, and in virtually any climatic circumstance. The relatively brief history of phytoremediation causes most field applications to remain largely experimental endeavors requiring careful monitoring, in-process optimization and management, and the possibility of failure to achieve target cleanup goals. To allow the required treatment period for most phytosystems (3–10 seasons), the site must not possess contaminant levels of acute hazard to neighboring communities or resources, which would dictate more immediate cleanup technologies. In addition, extremely high levels of most pollutants are not typically treatable by biological methods, because of toxicity and/or insufficient rates of removal or degradation. Phytoremediation is an effective option for situations when contaminants are limited to standard rooting depth (0–3 m) or if the material can be mechanically extracted and applied to a planted treatment facility. Mixed wastes, e.g., heavy metal and organic contaminants, may not be suitable for phytoremediation, as plants are rarely tolerant or capable of concurrent treatment of dissimilar chemical classes. In addition, there remain numerous chemical pollutants that are not effectively treated using currently available phytoremediation technologies.

CONCLUSION

Phytoremediation has gained great favor among concerned citizen groups and government regulators as a more affordable and less destructive method of pollution removal relative to intensely engineered technologies. These stakeholder groups have helped to drive field-scale implementation of phytoremediation treatments to allow further evaluation and development of this approach as a more commonly utilized tool for environmental remediation. The range and reproducibility of phytotechnologies will be improved with additional study and refinement of such field trials. For a wide array of pollutants, phytoremediation is an ecologically compatible, cost-effective alternative, or complementary option for standard engineered approaches. Extensive efforts are ongoing to extend the range of biological capabilities and technical application of phytoremediation systems.

Researchers have used biotechnological strategies to either enhance existing traits or confer novel capabilities to plants through genetic engineering. Biotechnological improvement of plants for phytoremediation was first described by transfer of bacterial mercury detoxification genes to plants with subsequent enhanced ability of the engineered plant species to extract and degrade hazardous mercury compounds, a capability not found in naturally occurring plants. Since this report, numerous laboratories have advanced the understanding of molecular genetic mechanisms and successful implementation of biotechnological improvement of plants for environmental detoxification. Phytoremediation will continue to grow as an effective remedial technology with further development of well-documented field trials and exploitation of powerful biotechnological approaches for enhancement of plant utility against more complex environmental hazards.

Phytoremediation: Advances Toward a New Cleanup Technology

Adel Zayed
Paradigm Genetics, Inc., RTP, North Carolina, U.S.A.

INTRODUCTION

Decades of unrestricted use, disposal, and release of industrial-, defense-, and energy production–related chemicals have considerably accelerated the pollution of our environment with radionuclides, toxic metals, and organic pollutants. Environmental exposure to such toxic chemicals is a serious health risk for humans and animals. Unfortunately, existing technologies for the cleanup of contaminated environments are very costly and/or limited in various ways. Cleanup of toxic metal contaminated soils with existing technologies costs up to $1,000,000 per acre without totally removing the pollutant from the environment. In the United States alone, the cost of cleaning up sites contaminated with toxic and radioactive metals is estimated to be $400 billion.

Phytoremediation, the process by which various naturally occurring or genetically modified plants, including trees and grasses, are used to degrade, extract, detoxify, contain, and/or immobilize toxic pollutants from contaminated soil, water, and air, offers an attractive and cost-effective solution for the clean up of contaminated sites. The potential economic benefits of using plants for remediation are impressive. Growing a crop on an acre of land can be accomplished at a cost ranging from two to four orders of magnitude less than the current engineering cost of excavation and reburial. Plants provide a robust, solar-powered system that has little or no maintenance requirements. With their copious root systems, plants can scavenge large areas and volumes of soils, removing the toxic chemical. The rhizosphere soil (soil near plant roots) has microbial populations orders of magnitude greater than bulk soil (nonroot soil). Furthermore, plant-based systems are welcomed by the public due to their superior aesthetics and the societal and environmental benefits that their presence provides. There are several different ways that phytoremediation can be achieved (Table 1).

Research into phytoremediation may offer the remediation solution for at least 30,000 contaminated sites in the United States alone. Phytoremediation is applicable to a number of hazardous waste and other remedial scenarios, including remediation of metals, organics, and radionuclides from soils and water, which together offer a total U.S. market opportunity of up to $10 billion. Phytoremediation is also potentially applicable to all types of water treatments including industrial, agricultural, and municipal wastewaters, landfill leachate, stormwater, and drinking water with a potential market opportunity of up to $40.7 billion (Table 2). Similar markets exist overseas, which are smaller but which offer greater long-term potential for growth.

TRANSGENIC PHYTOREMEDIATION APPROACHES

The ideal plant species for phytoremediation is one that can accumulate, degrade, or detoxify large amounts of the toxic chemical, grow rapidly on contaminated sites and produce a large biomass, tolerate salinity and other toxic conditions, and provide a yield of economic value, e.g., fibers. Metal hyperaccumulator plants occur naturally on metal-rich soils and accumulate metals in their above-ground tissues to concentrations between one and three orders of magnitude higher than surrounding “normal” plants grown at the same site. Unfortunately, most hyperaccumulator plants studied to date grow very slowly and accumulate little biomass. For phytoremediation to become a viable technology, dramatic improvements would be required in either hyperaccumulator biomass yield or nonaccumulator metal accumulation. The introduction of novel traits into high biomass or hyperaccumulator plants in a transgenic approach is a promising strategy for the development of effective phytoremediation technologies.

There are several conceivable strategies for the use of genetic engineering to improve phytoremediation. Strategies to improve metal phytoremediation involve the optimization of a number of processes, including trace element mobilization in the soil, uptake into the root, detoxification, and translocation within the plant. Strategies for enhancing phytoremediation of organics are potentially more straightforward and involve the introduction and/or overexpression of genes encoding biodegradative enzymes in transgenic plants to enhance their biodegradative abilities. In the last few years, progress has been made toward this goal and several types of
genetic modifications of plants for phytoremediation have been reported. For example, bacterial genes were transferred to plants to enhance their potentials for 1) phytovolatilization (e.g., transfer of \textit{merA} and \textit{merB} genes from bacteria into three different plant species to increase their tolerance to and volatilization of the toxic mercuric ion after its transformation into the much less toxic elemental mercury); 2) phytoextraction (e.g., transfer of \textit{gsh1} and \textit{gsh2} genes from \textit{Escherichia coli} to \textit{Brassica juncea} plants to increase Cd accumulation in shoots); and 3) detoxification (e.g., transfer of bacterial genes for removal of nitroso groups from explosive compounds into plants to detoxify trinitrotoluene, TNT). Another approach was to express mammalian genes in plants, e.g., genes encoding cytochrome P450 2E1, the liver enzyme responsible for activating trichloroethylene (TCE), resulting in an increase in TCE oxidation by two orders of magnitude. A more straightforward approach is to overexpress existing plant genes that control key-limiting processes in order to overcome these limitations and accelerate the phytoremediation process (e.g., overexpression of \textit{AtAPS1} in \textit{B. juncea} resulted in twofold increase in selenium accumulation and the overexpression of \textit{NtCBP4} in \textit{Nicotiana tabacum} resulted in 2.5-fold increase in Ni tolerance and two-fold increase in Pb accumulation). These examples provide dramatic evidence of the potential of genetically engineered plants for bringing the promise of phytoremediation to fruition.

**THE PHYTOREMEDIATION GENOME/PROTEOME**

The vast majority of plant genes affecting the remediation of toxic elements and organics have not yet been identified. Identification of these genes is vital to the success of the transgenic phytoremediation approaches. The recent completion of the \textit{Arabidopsis} genome sequencing project has paved the way for the development of high throughput functional genomic approaches to accelerate the determination of gene function. It is estimated that the \textit{Arabidopsis} genome contains 80–90% of all the phytoremediation genes and gene families found in any macrophytes that could be used in phytoremediation applications. The \textit{Arabidopsis} genome is estimated to have 25,500 genes in 11,000 gene families. Approximately

5% of the genome appears to encode membrane transport proteins responsible for the transport of metals and ions across plant plasma and organelar membranes.[7] These proteins are classified in 46 unique families containing approximately 880 members. In addition, several hundred putative transporters have not yet been assigned to families. Only a small number of these transporter proteins have their function fully characterized. The vast majority, however, have no known or presumed function, and genetic and physiological analyses will be needed to determine their functions and their relative contributions to toxic metal uptake and transport in plants.[4,7]

An analysis of the Arabidopsis genome using the amino acid sequences of proteins with known roles in remediation suggests that approximately 700 genes encode phytoremediation-related proteins (PRP). This portion of the Arabidopsis proteome has been termed the phytoremediation proteome and it consists of approximately 450 enzymes catalyzing redox reactions (e.g., cytochrome P-450s, oxygenases, and dehalogenases), approximately 250 transport proteins, and several metal-binding proteins, e.g., metallothioneins. The availability of the Arabidopsis genome and EST sequences and the identification of the phytoremediation proteome provide enormous opportunities to accelerate greatly our effort to clean up environmental pollution.[4]

**Table 2** Summary of the size of potential U.S. markets for phytoremediation

**PHYTOREMEDIATION IN CONSTRUCTED WETLANDS**

Constructed wetlands represent a cost-effective phytoremediation solution for the cleanup of large volumes of wastewaters contaminated with low levels of toxic trace elements. They offer an efficient alternative to conventional water treatment systems because they are 1) relatively inexpensive to construct and operate, 2) easy to maintain, 3) effective and reliable wastewater treatment systems, 4) tolerant of fluctuating hydrologic and contaminant loading rates, and 5) providers of green space, wildlife habitat, and recreational and educational areas. In addition, ecosystems dominated by aquatic macrophytes are among the most productive in the world, largely as a result of ample light, water, nutrients, and the presence of plants that have developed morphological and biochemical adaptations enabling them to take advantage of these optimum conditions. Furthermore, these ecosystems are highly rich in microbial activities and therefore have high capacities to decompose organic matter and stabilize toxic trace elements. Constructed wetlands have been used for many years with great success to remove conventional pollutants (e.g., nitrate and phosphorus) from agricultural nutrient-laden runoff, drinking water, and domestic wastewater. Recently, there has been increasing interest in using constructed wetlands for the treatment of industrial wastewaters and acid-mine drainage containing heavy metals and toxic trace elements. A recent study demonstrated the successful use of wetlands in this area where a 36-ha constructed wetland removed 90% of the toxic selenium from 10 million liters/day of selenite-contaminated oil refinery effluent.[8] Constructed wetlands remove metals primarily through immobilization of the sulfide for Cu, Fe, Mn, Zn, and Cd. Sulfides of most metals are very stable under the anoxic waterlogged conditions of the wetlands.[9] In the case of metalloids such as Se, the soluble ions are taken up by plants and volatilized as a less toxic gas. Less is known about the use of constructed wetlands for the removal of toxic organics or pesticides although recent studies indicate that wetlands efficiently remove some chlorinated compounds present at low levels that are difficult to remove by other means.[9] A significant amount of research is currently underway to determine the best wetland plant species, including algae and vascular plants, that can be used to maximize pollutant removal by wetlands.[10]

**FUTURE PROSPECTS**

New uses of plants are emerging as a result of the recent advances in agricultural biotechnology. Phytoremediation is one of these new uses that has been extensively and effectively tested in the cleanup of real contamination sites and is becoming commercially feasible. The technology is currently being adopted and promoted by several government agencies (e.g., U.S. Environmental Protection Agency), and field demonstration projects are currently underway in many “superfund” sites across the...
However, the existing knowledge about the rate and extent of degradation or extraction of pollutants by the phytoremediating crop is still limited, and specific data are needed on more plants, contaminants, and climate conditions. Additional progress in phytoremediation is likely to come from utilizing the recent genomic information to create new “superplants” overexpressing genes responsible for the removal, degradation, and/or sequestration of various contaminants. Further optimization of in-field performance of phytoremediation will require improvements in a number of agronomic practices, ranging from traditional crop management techniques to approaches more specific to phytoremediation, such as amendment of soil with chelators.

Pierce’s Disease and Others Caused by *Xylella fastidiosa*

John S. Hartung
USDA—ARS, Beltsville, Maryland, U.S.A.

**INTRODUCTION**

In the past decade, *Xylella fastidiosa* Wells et al. has become one of the world’s most important plant pathogens, causing devastating diseases of grapevine, sweet orange, coffee, almond, peach, plum, several shade trees, and oleander. The Gram-negative bacterium was formally named only in 1987, and is characterized by being nutritionally fastidious and extremely slow-growing in culture. These traits have made the pathogen difficult to study, and have contributed to its previous obscurity. Pierce’s disease (PD) of grapevine, (*Vitis vinifera* L.), caused by *X. fastidiosa* has recently reemerged as a major problem for the California grape industry because of the introduction of a new insect vector.

The Spanish introduced the European grapevine into southern California early in the 18th century, where it became the basis for an important industry. In 1884, the ‘‘Mission’’ grapevines in Anaheim suddenly began to die rapidly. The United States Department of Agriculture dispatched Mr. Newton B. Pierce to investigate and report on the disease in 1889. Pierce reported that this previously undescribed vine disease resulted from blockage of the water-carrying vessels in diseased plants. Pierce was unable to culture a pathogen from diseased plants, and he reported the novel observation of growers that grafting contaminated buds onto healthy vines could transmit the disease. He also noted that unlike the susceptible, higher-value European varieties, the North American grape varieties were tolerant or resistant to the disease.

**SYMPTOMS**

The initial symptom of PD is a leaf scorch that begins at the outer margins of the lower leaves, then progresses inward on the leaves and upward along the vine. Eventually the affected leaves fall, beginning at the bottom of the vine, but the petioles remain attached. Irregular “green islands” remain on the stem where the bark fails to mature properly. Fruit dries on the vine, and in susceptible varieties the disease leads to rapid vine death.[1]

**DISEASE EPIDEMIOLOGY AND IMPORTANCE TO VITICULTURE**

In the absence of a bacterium or fungus, PD was logically, though incorrectly, attributed to a virus for nearly a century. Early workers established important facts about the disease. First, the ‘‘PD virus’’ was shown to have an extraordinary range of plant hosts in California. This included 36 species belonging to 18 families that were naturally infected, and 75 species from 23 families that could be experimentally infected by insects.[2] However, the majority of hosts were symptomless carriers. The transmission of the pathogen by 20 insect species[3] was taken as further evidence that the pathogen was a virus, since insect transmission is typical of viral plant diseases. Leafhopper insect vectors (family Cicadellidae) feed exclusively in the plant xylem, consistent with Pierce’s initial observation that the primary pathology was a dysfunction of the xylem. The extraordinary range of hosts and vectors make PD exceptionally difficult to control.

PD is endemic throughout North America where grapevines are grown in areas without a cold winter. There is evidence that temperatures below 10°C reduce *X. fastidiosa* populations, while freezing temperatures help grapevines recover from infection. Cold winters prevent the pathogen from overwintering in adult insect vectors, since they are killed by cold temperatures. It is believed that PD originated in the southeastern United States, and was introduced into California with native grape species that were being evaluated for resistance to *Phylloxera* root weevils. Similar shipments of North American grape species were sent to Europe in the same era for the same purpose, but PD did not become established there.

The introduction of PD to California in 1884 caused the failure of the grape industry in the Los Angeles basin. The industry in northern California has suffered only intermittent severe PD outbreaks during the past century. Growers in the southeastern United States have never been able to grow *V. vinifera*, because PD has killed every attempted vineyard. The southeastern United States is the home of the glassy-winged sharpshooter, *Homalodisca coagulata* Say, the most effective insect vector for the bacterium. This vector is so effective because it overwinters...
as infective adults, allowing it to transmit the bacterium in early spring. This insect also feeds on mature wood, resulting in systemic infections. Introduced into California in the early 1990s, this insect has become established in at least nine counties, where it threatens the $30 billion grape industry.

**DETECTION, IDENTIFICATION, AND CONTROL**

*X. fastidiosa* can be detected and identified by serological methods as well as by the polymerase chain reaction. The bacterium can also be cultured in vitro,

[4]

but this takes several weeks. PD, like other diseases caused by *X. fastidiosa*, is difficult to control. Because the pathogen lives deep inside woody tissue, it is not affected by externally applied pesticides. Pruning of vines at the first sign of infection has provided some control in northern California, but will likely fail in the presence of the glassy-winged sharpshooter. Insecticides may be used to kill vectors, but they interfere with the long-term suppression of the vectors by other insects. PD management relies on planting *X. fastidiosa*-free grapevines, frequent monitoring of the vineyards, and removal of diseased vines before they can serve as inoculum sources. No useful levels of resistance have been found in varieties of wine grapes or in their rootstocks.

**OTHER DISEASES CAUSED BY Xylella fastidiosa**

Strains of *X. fastidiosa* cause important diseases of a wide range of perennial horticultural plants in North America. These include "phony" disease of peach, leaf scald of plum, and leaf scorch of almond, oak, maple, and mulberry.

[5]

Oleander leaf scorch has become a plant disease problem in the southwestern United States recently, killing oleanders that are widely used as horticultural barriers on highways. The outbreak of oleander leaf scorch coincided with the introduction of the glassy-winged sharpshooter.

Perhaps the most economically important diseases caused by *X. fastidiosa* are found in Brazil. Citrus variegated chlorosis (CVC) was first described in sweet orange in São Paulo State in 1987.

[6]

São Paulo is home to the largest sweet orange industry in the world, and currently 35% of the trees are infected with *X. fastidiosa*. The coffee industry in Brazil is also seriously affected by a disease known as requiema do café, also caused by *X. fastidiosa*.

[7]

Both diseases are now widespread in Brazil and occur in several other South and Central American countries.

Symptoms of CVC appear as a bright yellow leaf mottle resembling symptoms of zinc deficiency. Localized, brown lesions appear on the upper surface of affected leaves. These lesions extend through the leaf and a sticky exudate is found on the underside. Fruit on affected trees fails to fill to proper size and remains attached to the tree. In contrast with PD, CVC does not cause defoliation or leaf scorch and it is not fatal to the tree. Symptoms of requiema do café include progressive defoliation from the lower part of a branch upward and conspicuously shortened branch internodes. The fruit on affected coffee bushes fails to fill to proper size, but requiema do café does not kill affected bushes.

**THE Xylella fastidiosa GENOME**

The geographical range of *X. fastidiosa* throughout the Americas, and its wide range of economic and asymptomatic hosts, have led researchers to investigate the population structure of *X. fastidiosa*. These studies have revealed four or five clonal lineages associated with the geographical region and economic host from which the strains were first isolated.

[8]

Thus, although the pathogen can survive in a wide range of plants in nature, there are mechanisms acting to maintain separate clonal lineages associated with economic hosts.

The impact of CVC on the Brazilian sweet orange industry prompted the state of São Paulo to organize a consortium of researchers to study the pathogen. This effort led to the citrus strain of *X. fastidiosa* becoming the first plant pathogenic bacterium to have its genome completely sequenced.

[9] Analysis of the sequence data showed that *X. fastidiosa* lacks genes that are characteristic of many animal and plant pathogenic bacteria. These include genes that define and limit host range and those that encode the system required to export molecules involved in pathogenesis.

**CONCLUSION**

Conventional plant breeding to produce plant varieties resistant to *X. fastidiosa* is not practical for horticultural reasons. However, it may be possible to genetically engineer plants with resistance to *X. fastidiosa* by producing antimicrobial substances in the xylem fluid. In the case of grapevine or sweet orange, the genetic engineering could be done on the rootstock only, leaving the fruiting portion of the plant unaltered. This approach would more likely be accepted by consumers and would also be more efficient, since each grape or orange variety could be propagated on a common rootstock. However,
the possibility that the antimicrobial substances could accumulate in the fruit would have to be carefully monitored and addressed during the research and development phase of such a project, to ensure the safety of consumers.

The economically important hosts of \textit{X. fastidiosa} have been introduced into their respective ecosystems. In contrast, species native to these regions are commonly infected by the bacterium, but suffer no apparent ill effects.\cite{3} The pathogen exploits an unusual ecological niche, living only in the water-conducting vessels of plants and in the mouthparts of certain plant sap-feeding insects. These facts, and the observation that \textit{X. fastidiosa} lacks characteristic pathogenicity genes,\cite{9} have led to the suggestion that the bacterium may be an endophyte that has co-evolved with the flora of the Americas. Hence, the diseases caused by \textit{X. fastidiosa} could be viewed as nature’s way of defending the ecosystem from invasive plant species.\cite{10} A corollary of this view is that if \textit{X. fastidiosa} is an endophyte that is somehow out of balance with its host, then perhaps the diseases could be managed by biological control, using other antagonistic endophytic organisms.\cite{11}

INTRODUCTION

Plant cell cultures, also called cell suspension cultures, can be applied for the production of valuable pharmaceutical products. The large-scale cultivation technique of plant cells is similar to that of microbial suspension cultures. Plant cells can also be used as hosts for the production of mammalian protein products such as interleukins, monoclonal antibodies, and enzymes. In addition to its use as a production system for valuable compounds, plant cell cultures have been successfully employed for the development of mutants, production of polyploids, and genetic engineering of crops.

In the beginning of the 20th century, German botanist Gottlieb Haberlandt envisaged the possibilities and potentials of plant cell culture and made pioneering attempts to isolate and grow plant cells in culture. Since then, spectacular advancements have occurred in this field and plant cell cultures are now used for different industrial applications. It is now also possible to regenerate whole plants from single cells of a large number of plant species.

The use of isolated plant cells to investigate the physiological, biochemical, and molecular aspects of various cellular functions—especially in the absence of the influence of other cells—has been recognized for a long time. For instance, isolated plant cells have been extensively used for studies on photosynthesis, ion transport, secondary metabolite production, and cytodifferentiation. Plant cell cultures have also been exploited for the isolation of mutants, production of polyploids, and genetic engineering. However, from the current research trend, the most significant application of plant cell culture appears to be in the area of commercial production of industrial compounds.

Plant cells can be cultivated as suspension cultures in a large-scale bioreactor for the production of various primary and secondary metabolic products such as pharmaceuticals, food products, and agricultural chemicals. One of the major constraints for plant-cell based production systems is the low productivity of commercially attractive metabolites.

Another potential application of plant cell cultures is in the production of foreign proteins. Plant cells can offer advantages over mammalian cells because the plant cell medium is very simple and inexpensive. This article reviews large-scale cultivation techniques, secondary metabolite production, and foreign protein production from plant cell cultures.

LARGE-SCALE CULTIVATIONS

The first step in creating the suspension culture is to develop a callus culture, which can be initiated by placing a small piece of plant tissue on solid media containing nutrients, salts, vitamins, and growth factors. After several days, an unorganized amorphous mass of cells will develop on the plate. Plant suspension cultures can be initiated by adding well-developed calli into a liquid medium containing ingredients similar to the solid medium, with the exception of agar.

In the beginning of the 20th century, German botanist Gottlieb Haberlandt envisaged the possibilities and potentials of plant cell culture and made pioneering attempts to isolate and grow plant cells in culture. Since then, spectacular advancements have occurred in this field and plant cell cultures are now used for different industrial applications. It is now also possible to regenerate whole plants from single cells of a large number of plant species.

One of the major constraints for plant-cell based production systems is the low productivity of commercially attractive metabolites.

Another potential application of plant cell cultures is in the production of foreign proteins. Plant cells can offer advantages over mammalian cells because the plant cell medium is very simple and inexpensive. This article reviews large-scale cultivation techniques, secondary metabolite production, and foreign protein production from plant cell cultures.
problem with the airlift bioreactor is foaming. Cells tend to rise with the air bubbles, become trapped in the foam, and eventually die due to lack of nutrients. The addition of antifoam agents can reduce this problem, although the agents can also adversely affect cell growth.

THE PRODUCTION OF SECONDARY METABOLITES

Many secondary metabolites can be produced from plant cell cultures. These include alkaloids, flavors, fragrances, organic acids, and steroids (Table 1). Secondary metabolites are seldom produced during the active cell growth phase. They are normally produced during the stationary phase. The product either accumulates within the cells or leaks into the medium.

Some metabolites—such as anthocyanin, anthraquinone, berberine, rosmarinic acid, and shikonin—can be produced with a higher titer than those in the parent plants. For example, shikonin can accumulate up to 14% of dry cell weight in plant cell cultures compared to 1.5% in a whole plant.

However, the major hindrance in the development of commercial processes is the low productivity of secondary metabolites from cell cultures. Therefore, a plant-cell based process can only be justified if it offers an economic advantage over chemical synthesis or traditional extraction processes, or if no other alternative production route exists.

The production levels of secondary metabolites can be improved by adding elicitors to the medium, selecting the best cell line, optimizing the medium formulation, and designing the most appropriate bioreactor. However, efforts to further increase the level of metabolite production are obstructed by lack of basic knowledge of biosynthetic routes and the mechanisms regulating metabolite accumulation, which also prevents the use of modern metabolic or genetic engineering techniques.

THE PRODUCTION OF FOREIGN PROTEINS FROM GENETICALLY MODIFIED PLANT CELLS

Instead of producing natural metabolites, plant cells can be employed as host cells to express mammalian proteins. Several research groups tested the feasibility of producing foreign protein products such as immunoglobulin, monoclonal antibodies, enzymes, interleukins, and vaccines by genetically modifying tobacco cells.

There are several advantages to using plant—rather than mammalian—cells for the production of foreign proteins. Plant cell media are composed mainly of simple sugars and salts and are much less expensive than complex mammalian media. It is therefore much easier and more economical to purify secreted transgenic proteins from plant cell media. Additionally, owing to their rigid exterior walls, plant cells are more resistant than mammalian cells to the shear forces involved in large-scale cell culture. Furthermore, plant cell-derived transgenic proteins are likely to be safer for human use than those derived from mammalian cells, because plant cell contaminants and viruses are not pathogenic to humans.

In general, foreign proteins produced from genetically modified plant cells are correctly folded, glycosylated, and biologically active. The foreign proteins tend to be produced during the exponential growth period of batch cultures and secrete into the medium for separation more easily than do intracellular proteins. The level of intracellular transgenic protein production ranges from 0–0.28 mg/L culture, and that of extracellular protein released into the medium ranges from 0–2 mg/L culture. The percent of extracellular transgenic product relative to the amount of total soluble protein released into the medium ranges from 0–0.84%.

</tr>
</thead>
<tbody>
<tr>
<td>Foreign proteins</td>
<td>Enzymes, interleukins, GM-CSF, monoclonal antibodies, vaccines</td>
</tr>
</tbody>
</table>
The productivity of foreign proteins from plant cell cultures is significantly lower than that of animal cell cultures. However, it is still too early to draw any definitive conclusions in this regard because the research efforts in plant host systems have barely begun. Based on our research findings, this low productivity may be due to the protein instability in plant cell media and low expression levels of mammalian genes in plant cell host systems.[7] Nevertheless, when making the above comparisons of transgenic protein production, we must consider that the cost of plant cell media is several orders of magnitude lower than the cost of animal cell media. Furthermore, the cost of the downstream processing of plant cell cultures is also significantly lower than that of animal culture systems. Therefore, plant cell systems may be economically competitive with animal culture systems, even at their current production level.

CONCLUSION

The field of plant cell culture has witnessed remarkable progress in the past few decades. Methods for the establishment of cell cultures and for regeneration of plants from single cells are now available for a large number of plant species. Plant cell cultures have been successfully used for the development of mutants and for molecular plant improvement, and their use as a system for the production of natural plant metabolites or foreign protein products is gaining considerable momentum. One major hindrance for commercial application is their low productivity, which must be overcome before the plant-cell based production system comes an economically viable process.

INTRODUCTION

In 1904 Hannig isolated immature embryos in vitro from several members of the brassicaceae and recovered fertile plants. Since then a range of plant culture techniques has been developed. These techniques are based in part upon the ability of plants to reproduce asexually (vegetative reproduction). Familiar examples would include potato tubers, offsets produced by bulbous plants and cuttings that can be rooted and established as new plants. For many plants, specialized techniques have been developed that allow for the multiplication of isolated cells, tissues, and organs. These techniques share a set of common characteristics; principal among them is that they are conducted using some form of culture vessel. Initially vessels were of glass construction, hence the term in vitro, literally meaning “in glass.” Plant culture techniques range from relatively simple systems such as the sowing of orchid seeds in vitro to the regeneration of whole plants from isolated protoplasts, ovules, or microspores (from immature pollen). These diverse methodologies are grouped under the term “plant cell, tissue, and organ culture,” although the terms “in vitro culture of plants” and “plant tissue culture” are also used. These methodologies are defined as the culture of isolated plant parts that include whole plants, seeds, embryos, organs, tissues, cells, protoplasts, and microspores (or in) a nutrient medium under aseptic conditions. In addition to performing plant tissue culture in vitro, the techniques are further characterized by several other features:

- The environmental conditions are optimized with regard to physical (temperature and light period and quality) as well as nutritional and chemical (plant growth regulators) factors.
- Microorganisms, particularly bacteria and fungi, are excluded, as are other pests such as insects.
- The normal pattern of plant development is usually interrupted; isolated cells, tissues, and organs may enter new patterns of development that lead to regeneration of new organs or result in the formation of embryos.

This article describes various techniques and concepts of plant cell, tissue, and organ culture.

PLANT TISSUE CULTURE TECHNIQUES

In vitro culture of plants has been applied as a practical tool in agriculture and horticulture and as a technique in many studies of plant biology. The basis of these applications is the ability (at least in theory) to clone or proliferate plant cells, tissues, and organs in large numbers. Ultimately, complete new plants can be produced from either preexisting shoot buds and meristems, or following regeneration via shoot organogenesis (morphogenesis) or through embryogenesis. The process of regeneration from cells that would not normally have participated in such events is an indication that plant cells are ‘totipotent’, retaining a latent capacity to reproduce a whole plant from somatic cells. Totipotency, however, is not a universal property of all plant cells.

The various techniques of plant tissue culture can be classified simply into organized and unorganized cultures with respect to the morphology of the established culture (Table 1). Strictly, unorganized cultures are tissue cultures, although the term is often used more generally to include all culture types. Organ culture generally describes cultures in which some form of organized growth is maintained, as in the continued growth of shoot or root apices. The definitions are not mutually exclusive, and organized cultures can contain mixtures of single cells and unorganized cell clumps, as well as organized structures. Equally, unorganized cells may also be induced to organize and regenerate plant organs through organogenesis or embryogenesis.

Regeneration via organogenesis or embryogenesis may take place either directly from isolated cells, tissues, or
organs or following an intervening callus/tissue phase. Direct regeneration may occur from isolated tissues or organs that regenerate shoots or roots, or from cells induced to form embryos. Indirect regeneration occurs following the proliferation of unorganized cells established in tissue (callus) or cell suspension culture, and may also occur from semiorganized callus or nodules produced on pieces of tissue or organ isolated in culture.

**REQUIREMENTS FOR PLANT CELL TISSUE AND ORGAN CULTURE**

Cultures are started from small pieces of plant material usually referred to as explants. Plant cells will only grow in culture when provided with specialized media. Typically, culture media consist of mineral salts for supplying the macro- and micronutrients, and a carbon source (usually sucrose). Vitamins and amino acids in the culture medium may improve growth but are not essential. Growth and development of plant cultures usually depends on the addition of plant growth regulators (PGRs). These compounds, both natural and synthetic, are capable of modifying plant growth and development (morphogenesis) at very low concentrations. Many culture media formulations have been developed for specific techniques or individual species. A formulation developed by Murashige and Skoog has been used more widely than others.

Plant material may be cultured in a liquid medium or in a semisolid medium partially solidified with a gelling agent such as agar or gellan gum. Cultures grown in a semisolid medium are kept static, whereas liquid cultures are usually agitated to ensure adequate gaseous exchange. Bioreactors have been developed in conjunction with liquid media to facilitate scaled up operations. Promising results have been obtained recently with temporary immersion vessels.

![Table 1 Classification and types of plant cell, tissue, and organ cultures](P.png)
Plant culture media can also support the growth of microorganisms; consequently they are sterilized prior to use, usually by autoclaving. Components of media susceptible to degradation at high temperature are filter-sterilized and added after autoclaving of the media. Manipulations of culture media and plant material are carried out in laminar-flow cabinets that provide sterile working environments. Plant cultures are incubated in controlled-environment growth cabinets.

**GENERAL METHODOLOGY USED IN PLANT CULTURE**

The processes of plant tissue culture have been divided into five stages (0–IV), as shown in Table 2. The stages are useful for defining the procedural steps, and here we have identified the critical aspects of the biology at each stage for the principal culture techniques illustrated in Fig. 1.

**Stage 0: Pretreatment of Motherplant and Explant**

Attention must be paid to selection of appropriate starting material. In general, problems with infection of the cultures are greater with material taken from plants grown in the field than with plant material maintained under controlled environments. Growth, morphogenesis, and rates of propagation can be improved by appropriate environmental and chemical pretreatment of stock plants.

**Stage I: Establishment of Aseptic Culture**

Choice of starting material will depend on the technique used and the plant species being cultured. Material should be disease-free and capable of active growth. Material taken from seedling parts (such as hypocotyls or cotyledons) is usually more responsive than material from mature adult plants. During establishment, the aim is to obtain an aseptic culture of the plant material. Surface sterilization of plant material is achieved through aqueous washing in germicidal agents such as alcohol or hypochlorite. Solutions of sodium and calcium hypochlorite containing between 0.25–1.5% available chlorine are commonly used. Traces of the surface sterilant are removed from plant material by washing several times in sterile distilled water. Explant preparation leads to the induction of wounding responses, some of which can be detrimental to the continued growth of the culture. In these circumstances material may be treated with antioxidants or adsorbents to remove toxic compounds. Antibiotics and fungicides are sometimes used to remove or control contaminants that occur in established cultures. A full account of the procedures used can be found in George.[2]

In addition to achieving aseptic cultures, the establishment stage aims to initiate growth of the culture as well. This may involve the use of stress treatments, including cold, osmotic, and nutrient starvation. Such stress treatments are common for the induction of embryogenesis in isolated cells, particularly for androgenesis and gynogenesis. Plant growth regulators usually play an important part in the induction of organogenesis and embryogenesis, with auxins and cytokinins, often employed to induce them, either singly or in combination.

**Stage II: Generation of Suitable Propagules**

This stage concerns the generation of new plant units (propagules) that can give rise to whole plants. These could be axillary or adventitious shoots; branched or adventitious roots; haploid, double haploid, or somatic embryos; or storage or propagative organs (Fig. 1). Propagules may be derived via organogenesis, by shoots, roots, storage or propagative organs produced adventitiously, or by their de novo formation from callus, nodules, meristems, or suspension cultures. Alternatively, propagules may be derived via somatic embryogenesis, androgenesis, or gynogenesis, wherein reprogramming of the cells occurs, to form embryos from somatic cells, microspores, or ovules, respectively. Cytokinins are frequently involved in shoot production and proliferation, whereas growth regulators are often reduced in concentration or omitted for embryogenic development. Some propagules produced during stage II are used in further rounds of multiplication to increase the number of propagules.

**Stage III: Preparation for External Environment**

In the external environment, the plant material will be required to photosynthesize and survive away from an artificial supply of carbohydrate. Storage and propagative organs may need little if any preparation for this stage;
however, shoots must be of adequate size and may be rooted prior to transfer. Some species form adventitious roots on shoots in culture, but are frequently induced by supplying exogenous auxin to the culture media. In root cultures, shoots are regenerated prior to planting out. Culture-derived embryos sometimes spontaneously convert (‘‘germinate’’) into plantlets, whereas in other instances they may need to be induced to convert. In some instances, encapsulated propagules are planted out as synthetic seed.\[7\]

**Stage IV: Acclimatization in External Environment**

Plants growing in tissue culture have often been exposed to high humidity and low light levels, which may result in poor development and limited photosynthetic capacity on transfer to the external environment. Agar is usually washed from the roots prior to planting and the plants are gradually acclimatized to higher light levels and lower humidity. Some shoots are rooted directly in the weaning stage and not in aseptic culture.

**CONCLUSION**

A wide range of techniques for the culture of isolated plant cells, tissues, and organs has been developed, as illustrated in Fig. 1. Although they share a set of common features, the underlying biology of the various techniques differs greatly. Various methods are used in the commercial production of a wide range of plant species, including ornamentals, agricultural and forestry species, and natural plant products.\[8–11\] The techniques are also a core research tool for manipulation of gene function and regeneration of transgenic plants. From their beginnings a century ago, plant cell, tissue, and organ cultures have emerged as important practical tools that have provided fundamental insights into the biology of plants.

Plant Defenses Against Insects: Constitutive and Induced Chemical Defenses

Linda L. Walling
University of California, Riverside, California, U.S.A.

INTRODUCTION

Plants have elaborate mechanisms to recognize pathogens and pests and to deploy defense strategies to limit damage. Effective defenses maximize survival from immediate and future challenges and should not significantly compromise plant vitality, longevity, or reproductive success. To achieve this goal, plants utilize two lines of defense to control insects and mites. Both constitutive defenses (constantly expressed) and induced defenses (transiently expressed) channel carbon and nitrogen resources from vegetative and reproductive growth into protective mechanisms. The balance of constitutive and induced responses provides the plant flexibility to cope with a single stress or multiple environmental stresses that occur simultaneously. There are several recent reviews that provide molecular and ecological perspectives on plant defenses to insect and mite feeding.

The constitutive and induced defenses encountered by insects are dependent on their mode and site of feeding. Some insects cause tissue damage by crushing, tearing, rasping, or lacerating plants cells. Other insects use less destructive modes of feeding (piercing and sucking) to consume cellular fluids. It is not surprising that the constitutive and induced defenses encountered by tissue-damaging and piercing/sucking insects are often distinct. While chewing insects release stored chemical defenses, piercing/sucking insects encounter stored chemicals only if they damage cells along the path to their feeding site.

CONSTITUTIVE DEFENSES

Constitutive defenses include both physical barriers and stored chemicals.[1] The cuticle and plant cell wall form the front line of plant defense. Cell wall composition and species-specific compounds that reinforce the wall (lignin, tannins, silicon, suberin) can make it difficult for insects to tear, chew, or penetrate tissue to reach feeding sites, such as the phloem or xylem. The chemical composition and cross-linking of cell wall constituents change after attack, making it a more formidable barrier for subsequent microbial or insect invaders.[2] "Plant Defenses Against Insects: Physical Defenses" provides additional details.

Stored chemicals (secondary metabolites) can influence insect growth, development, reproduction, survival, or colonization of plants.[3] The chemical nature and location of these chemicals is dependent on the plant species, organ, or cell-type, and levels can increase after insect feeding. Genes that control secondary metabolite accumulation can be utilized in breeding programs to enhance insect resistance.

Trichomes (leaf hairs) act as physical barriers and chemical storehouses. Trichomes can impale or interfere with the movements of small insects, including insect predators and parasites. Trichomes and secretory glands are also rich sources of chemicals that are insect deterrents and can reduce insect feeding, oviposition, growth, or viability. See "Plant Defenses Against Insects: Physical Defenses" for details.

Finally, many defense compounds are stored as inactive glucose-conjugated molecules and are activated only after tissue damage. For example, over 2500 plant species store glucose-conjugated hydrogen cyanide (HCN) precursors and their activating enzymes in separate cells or cellular compartments.[4] Upon insect attack, these molecules mix to produce HCN, a potent toxin. Another example is the glucose conjugates of hydroxamic acid (Hx-Glu), which are correlated with resistance to phloem-feeding and tissue-damaging insects.[5] Hx-Glu levels are highest in young monocot leaves, which need enhanced defenses; young leaves are the preferred site for insect feeding due to their high levels of soluble nitrogen-containing compounds. Older leaves are also protected because Hxs are induced after insect attack.

INDUCED DEFENSES

Insects are active participants in plant-insect interactions. Insects introduce oral secretions into feeding sites. Some compounds (elicitors) in these secretions stimulate defense signaling and volatile production, while other elicitors clearly suppress defense mechanisms. Therefore, induced defenses are complex, often resulting in changes...
in plant gene expression or volatile emission that are specific for a insect plant interaction.\textsuperscript{6–9}

The duration and intensity of the mechanical and chemical signals generated in each plant-insect interaction influences the nature of the local-and systemic-induced defenses. Plants respond to insect elicitors by modulating levels of plant-produced defense signals, such as salicylic acid (SA; an aspirin derivative) and jasmonic acid (JA) (Fig. 2). SA and JA control opposing defense strategies, which are not mutually exclusive. The magnitude and duration of the increases in JA and SA determine which defense pathways are activated. With tissue-damaging insects, JA-mediated wound responses often predominate; this provides a systemic protection against insects and increased susceptibility to pathogens. With insects that do little tissue damage, SA-mediated or JA-mediated bacterial defenses are activated, providing enhanced protection against pathogens and susceptibility to tissue-damaging herbivores.\textsuperscript{1,7} See “Plant Responses to Stress: Role of the Jasmonate Signal Transduction Pathway” for details.

**Activation of Wound Responses**

The insects that damage plant tissue induce changes locally (in the damaged tissue) and systemically (in non-damaged tissue) (Fig. 1). The local wound response facilitates healing at the wound site and restoration of cellular homeostasis by increasing cell divisions, cell wall synthesis, and basal metabolism.\textsuperscript{3}

Wounding also causes the release of the lipid linolenic acid from plant membranes. Linolenic acid is used to synthesize a variety of biologically active oxylipins, including 12-oxo-phytodienoic acid (12-OPDA) and jasmonic acid (JA) (Fig. 2). These oxylipins induce a set of genes (including the bioactive wound peptide gene prosystemin) that amplify the octadecanoid (oxylipin) pathway in damaged leaves.\textsuperscript{1,10} Analyses of mutants that cannot perceive or produce abscisic acid or ethylene have shown that these phytohormones are essential for the wound response. In contrast, as described above, SA antagonizes the wound response (Fig. 2).

While JA, systemin, and 12-OPDA are important in activating wound-response genes in the damaged leaf, the nature of the signal that activates systemic wound responses remains controversial. Current data indicate that systemic signaling must rely on enhanced perception of oxylipins or a novel chemical signal\textsuperscript{11} (Fig. 2). Hydrogen peroxide, electrical signals, and hydraulic signals are also possible modulators of systemic wound responses.\textsuperscript{10,12}

Many wound-response proteins and secondary metabolites directly interfere with insect feeding or have

---

**Fig. 1** Constitutive and induced defense responses to insect feeding. Insects encounter constitutive defenses at the site of feeding. Upon feeding, insects provide mechanical signals, introduce chemical signals from their oral secretions at their feeding site, and/or stimulate plants to produce signals that activate defense responses locally and systemically. This often results in a systemic resistance to further attacks. The nature of the systemic signals is unknown at the present time. Genes may be suppressed or activated. Induced proteins and chemicals may have antinutritive or antifeeding effects (direct defense) or may stimulate volatile release, influencing insect densities and attractiveness to natural enemies (indirect defense).
antinutritive effects.\textsuperscript{[1,6,10,13]} Anti-feeding compounds (alkaloids, C$_6$ volatiles, phytoalexins) limit plant injury. Anti-nutritive compounds (proteinase inhibitors, polyphenol oxidase, proteases) reduce food quality or digestibility. These compounds restrain insect population expansion by slowing insect development and increasing the time available for attack by predators and parasites. Not surprising, plants that have increased or decreased levels of wound-response proteins (i.e., lipoxygenase, proteinase inhibitors, or polyphenol oxidase) have enhanced resistance or susceptibility to insects, respectively.

**Activation of Pathogen-Response Pathways**

Piercing/sucking insects use modified mouthparts called stylets to consume large quantities of fluids from plant cells to recover nutrients.\textsuperscript{[1]} The feeding sites may be veins of the phloem (whiteflies, aphids, mealy bugs, psyllids), epidermal and mesophyll cells (thrips), mesophyll parenchyma (scale insects), or xylem (leafhoppers). The amount of damage caused by piercing/sucking insects varies considerably.

The piercing/sucking insects that cause little tissue damage (whiteflies, aphids) activate different signaling pathways than tissue-damaging insects and appear to be perceived as pathogens.\textsuperscript{[1]} Wound responses are not activated or are present transiently. Furthermore, these insects induce pathogenesis-related protein (PR) genes, which are usually induced by microbial pathogens. Their roles in insect defense are not understood. PR genes are regulated by a variety of defense signals including JA, ethylene, SA, and reactive oxygen species. Recent insect-plant studies indicate that even closely related insect species deliver different chemical or mechanical signals to plants, which are translated into distinct changes in plant gene expression.\textsuperscript{[1,9]}

---

**Fig. 2** Molecules important in defense-response signaling in plants. Linolenic acid is released from membranes after insect feeding and is catabolized via hydroperoxide lyase to produce C$_6$ volatiles (Fig. 3) or the octadecanoid pathway to produce a series of biologically active oxylipins, including 12-OPDA and jasmonic acid. The octadecanoid pathway increases the levels of the wound peptide systemin. Systemin, JA, and 12-OPDA enhance local expression of wound-response genes encoding proteins that have antinutritive or antifeeding effects. Systemin is an 18-amino acid peptide derived from prosystemin that activates the wound response. The amino acid sequence is shown using the single letter amino acid code. Ethylene, abscisic acid, and salicylic acid are known regulators of the octadecanoid pathway. Volicitin is an elicitor of volatile production found in lepidopteran oral secretions. It is formed by modifying the plant-derived linolenic acid.
Volatile Synthesis and Release

In response to insect and mite attack, wounding or JA treatment, plants release a complex blend of volatiles.\textsuperscript{[1,8]} Six-carbon (C$_6$) volatiles (the odors of freshly cut grass) are released after wounding and are generated from linolenic acid (Fig. 3). The C$_6$ volatiles listed in Fig. 3 are known to influence insect reproduction or feeding (for a review, see Ref. 1). Some C$_6$ volatiles serve as insect attractants. Terpenoids are major constituents of the volatile emissions after insect or mite attack (Fig. 3). In addition, methyl salicylate, indoles, nitriles, and oximes are commonly detected (Fig. 3).

The quantities of each compound in a volatile blend creates important species-specific cues for insects, mites, and their natural enemies. Volatiles dictate insect feeding densities and attract insect parasites and predators. Predators/parasites are able to discriminate between the volatile emissions from plants that are healthy, wounded, or infested with a host or nonhost insect.

Since the volatile blend emitted during each plant-insect interaction is unique, volatile synthesis must be influenced by insect-specific signals. Two elicitors of volatile production are known: volicitin and $\beta$-glucosidases. The discovery of volicitin has changed our perceptions of insect elicitors (Fig. 2). Volicitin is made from plant-derived linolenic acid, which is modified in the insect and subsequently reintroduced into the site of feeding via insect oral secretions.\textsuperscript{[14]} This coordinated biochemical initiative of the insect and plant is unique.

CONCLUSION

A broad range of technologies in molecular biology, genetics, and chemical ecology are currently being
applied to understand the complexity of plant responses to insect attack. These technologies will certainly be used to investigate the chemical diversity and biochemical origin of the elicitors in insect oral secretions that stimulate or suppress host-plant defenses. Integrated with the rapidly expanding knowledge about plant responses to known defense signals, such as JA, SA, ethylene, and reactive oxygen species, we will soon understand the nature and balance of the signaling pathways induced and suppressed by insects. These data will be useful to understand the cross-talk between insect-and pathogen-defense signaling pathways that ultimately dictate the antinutritive and anti-feeding compounds that accumulate after attack. It is anticipated that these findings will identify novel mechanisms that can be used in classical or molecular breeding strategies to enhance plant defenses to insect feeding.

INTRODUCTION

Only nine of the 29 insect orders include plant-eating species or phytophages, suggesting there are unique challenges facing potential herbivores. Four principal challenges can be identified: 1) the exceptional hardness and toughness of many plant tissues; 2) the problem of obtaining adequate attachment to the surfaces of plants in order to feed or oviposit; 3) the nutritional deficiency of plant tissues as a sole source for building animal bodies; and 4) the diverse and abundant secondary chemicals in many plant tissues that appear to serve as plant defenses. The first two of these challenges are physical.

The degree to which the physical properties of plants have been shaped to provide defense against insects is difficult to ascertain. Certainly, stiffened or hardened tissues that support the aerial plant organs and a tough, waterproof integument are requisite for successful exploitation of a terrestrial environment. Nonetheless, these characteristics demonstrably limit insect herbivory and have apparently provoked the evolution of specialized adaptations by phytophagous insects for coping with plant physical characteristics. This article reviews the physical plant characteristics that have been shown to impart defense against insect herbivores.

TOUGHNESS AND HARDNESS OF PLANT TISSUES

Plant tissues are both tough and hard. Toughness is measured in terms of resistance to shearing, whereas hardness is measured in terms of a material’s resistance to deformation. Structural polysaccharides in plants (cellulose, hemicelluloses, and pectins), lignin (various polymers with phenylpropane units), and cutin and suberin (polymers saturated and unsaturated long-chain fatty acids) are tough materials that resist shearing. The polysaccharides and lignin contribute to the stiffening of all cell walls, especially in vascular tissues, whereas cutin comprises the protective cuticle covering the primary epidermal cells of fruits and other reproductive structures, leaves, and shoots. Suberin performs a similar function for the epidermis of roots. Some plant tissues, notably within Gramineae, are infused with crystals of silica, or other hard minerals.

ADAPTATIONS

The majority of plant-feeding insects do not digest cellulose and other hard or tough materials but must process these tissues to access nutrients in the plant cytosol. Chewing insects must be able to shear these materials to remove pieces of plant material and crush or lacerate the cells to extract nutrients. Adaptations to achieve this include unique forms of mandibular teeth and powerful adductor muscles. The enlarged and strongly sclerotized head capsules of larval lepidoptera, symphyta (sawflies), and phytophagous coleoptera, and attine ants specialized for cutting leaves are evidence for this type of adaptation.

In addition to being tough, structural materials in plants are hard. Hardness causes physical wear to mandibular dentition. Microscopic examination of chewing insects reveals dramatic erosion of mandibular dentition as a result of a few weeks of feeding on hard plant tissues.[1] Hardness and toughness potentially act synergistically to impede chewing herbivores. The force required to shear a material is considerably greater with a dull rather than a sharp mandible. The tips of the teeth on some phytophagous insects are infused in turn with their own mineral constituents, including zinc and iron, as an apparent response to the challenge of feeding on hardened plant tissues.[2]

Other strategies for dealing with toughened tissues include those of homopterans and heteropterans adapted for extracting phloem or xylem tissues, and mites and thrips, which lacerate plant epidermal cells to extract nutrients. These strategies largely circumvent the problem of cutting or shearing large amounts of cell wall. Some of the earliest insect herbivores—the Paleodictyoptera—extracted nutrients from plants by piercing and sucking, possibly to cope with plant toughness and hardness.

Typically, plant toughness is measured crudely, using a penetrometer that measures the maximum force required to pierce plant tissue. This method has been criticized because it undoubtedly does not measure the physical factors that come into play precisely during mastication of
plant tissue by an insect. Nonetheless, there are good examples in the plant resistance literature in which plant toughness measured this way has been related to susceptibility to chewing injury.\[^3\]"

**SURFACE STRUCTURES INFLUENCING ATTACHMENT AND HERBIVORY**

The epidermis of plants is often covered with hairlike structures known as trichomes. Trichomes may be simple filaments or branching structures, minute and supracellular or large and multicellular, sparsely distributed or forming a dense pubescence on the plant surface. Some are complex structures that terminate in single- or multicellular secretory glands. Trichomes have been shown to be involved in defense against insects.\[^4\] The density, erectness, length, and shape of trichomes can influence their effects on insects. Trichomes may impart defense by forming a barrier that prevents some insects contacting the plant surface. Trichomes tend to be composed of a high proportion of cutin with relatively little cytoplasm. As a result, trichomes contribute to overall plant toughness and toughness of the plant integument, therefore interfering with ingestion. Simple trichomes can also interfere with attachment by feeding or ovipositing insects, and by eggs laid on the leaf surface. Individual insect-plant associations are differently affected by the presence of trichomes. This was assessed by Webster and by Norris and Kogan,\[^5\] who reviewed the results of 59 reports in the host plant resistance literature comparing insect attack on pubescent and hairless or glabrous varieties of crop plants. In 32 of these cases, trichomes provided some kind of resistance against insects, but in 13 cases trichomes conferred increased susceptibility (the remainder of the cases were equivocal). Most of the cases in which trichomes conferred susceptibility involved increased oviposition preference for pubescent plants. Apparently, some herbivorous insects have adapted to cope with plant trichomes. For example, the dense vesture of trichomes on the lower surface of *Quercus ilex* cause the aphid *Myzocallis annulatus* to frequently fall from this surface, whereas the *Q. ilex* specialist *M. schreiberi* walks freely on the plant.\[^6\]

Modified trichomes with hooks or secretory glands can affect insects uniquely. Hooked trichomes can help climbing plants attach to supports. In *Phaseolus vulgaris*, hooked trichomes have also been shown to provide protection against leafhopper nymphs by fatally impaling them.\[^7\] The exudates of glandular trichomes may be sticky and trap small insects. In *Solanum* and *Lycopersicon*, the stickiness is caused by polymerization of phenolics catalyzed by polyphenol oxidases. Substrate and enzyme are compartmentalized in the trichome gland but come into contact and react when insects rupture the glands during feeding. Trichome exudates also often contain topical toxins, repellents, or deterrents that contribute to defense against insects. Although these are beyond the scope of this article, they can work in concert with the physical characteristics of trichomes to enhance defense. For example, in *Solanum berthaultii*, sesquiterpenes produced by one type of glandular trichome cause aphids to move more rapidly, thus making it more likely for them to become trapped in sticky exudates produced by another type of glandular trichome.\[^8\] The cuticles of terrestrial plants are covered with a layer of long-chain hydrocarbons, related long-chain oxygenated alkyl compounds, and other lipophilic chemicals known as epicuticular waxes. These materials undoubtedly play a primary role in waterproofing the cuticle, but they can also influence insects on plants.\[^9\] Epicuticular waxes sometimes occur as dense vestures of minute crystals or wax blooms that confer a whitish appearance to the plant surface. Prominent wax blooms typically occur on crop plants such as *Brassica* spp., *Sorghum bicolor*, and peas. Such wax blooms can strongly reduce the ability of insects to attach to the plant surface, thereby providing some protection against herbivory. As a result, crops with genetically reduced wax blooms are more susceptible to certain insects.\[^10\]

**INDUCIBILITY OF PHYSICAL DEFENSES**

Plant defenses against insect herbivores are frequently inducible in response to insect feeding, and physical defenses apparently are no exception. Both trichome density\[^11\] and leaf toughness\[^12\] have been reported to increase following herbivory. As is true for other types of defenses, induced trichome density can be species-specific; for example, feeding by larvae of the cabbage butterfly *Pieris rapae* induced increased densities of trichomes in black mustard, *Brassica nigra*, whereas equivalent injury from flea beetles, *Phyllotreta cruciferae*, had no such effect.\[^11\]

**EFFECTS OF PHYSICAL DEFENSES ON INSECT NATURAL ENEMIES**

The net defensive effect of most plant characteristics depends not only on their direct effects on insect herbivores, but also on how these characteristics influence the natural enemies of the herbivores. The effect of trichomes and wax blooms on insect herbivores is complicated because these features can also disrupt attachment or impair the mobility of predators and parasitoids. For example, on a range of *Brassica oleracea* genotypes varying
in surface waxes, the effectiveness of two predator species was significantly correlated with the attachment forces these predators could generate on the plant surfaces.\(^{[13]}\) Wax blooms on some of these genotypes reduced predator attachment forces by as much as two orders of magnitude and severely impaired predator mobility. Apparently as a result of this type of interaction, genetic variants in \textit{Brassica} spp. and in peas with reduced wax bloom are more resistant to certain types of herbivory in the field than are varieties with typical waxy bloom [Rutledge, 2002 #3734]. Both simple and glandular trichomes also have been found to impede natural enemies. Repeatedly, in solanaceous crops and wild species, it has been shown that glandular trichomes producing sticky exudates trap predators and parasitoids, thereby reducing the effectiveness of these natural enemies at suppressing herbivores. Simple trichomes also can alter predator and parasitoid movement patterns and affect their ability to locate prey.

CONCLUSION

Whether physical characteristics of plants have evolved as defenses against insect herbivores is difficult to ascertain. Nonetheless, certain plant physical factors negatively affect herbivores and reduce herbivory. Some of these characteristics have been harnessed by plant breeders as part of their efforts to breed crops with resistance to insects. The possible negative effects of some physical factors such as toughness and trichomes on crop plant quality complicate these breeding efforts. In addition, individual herbivore species respond differently to physical characteristics. Moreover, some physical characteristics have strong effects on the natural enemies of insect herbivores, further complicating the net effects of physical traits on insect herbivory. Thus, as is the case with most efforts to achieve crop protection through breeding, it is necessary to understand the response to physical factors by at least the dominant species in the arthropod community targeted for management.

Plant Defenses Against Insects: Role of Endophytes

Stanley H. Faeth
Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

Endophytic fungi are a remarkably diverse and abundant group of microbes that live asymptotically, at least for part of their life cycle, within host plant tissues. As such, insects that feed upon plant tissues regularly encounter endophytic infections, or their chemical byproducts. Because some endophytes produce mycotoxins, they were originally envisioned as host plant mutualists by providing defense against insects and vertebrate herbivores. However, accumulating evidence suggests that many, if not most, endophytes have neutral or even positive effects on insects, especially specialists. For horizontally transmitted (via spores or hyphae) endophytes, transmission and colonization may be facilitated by insects, and thus evolution of strong antagonistic effects on insect herbivores is not expected. Defense against insect herbivores was originally envisioned as especially strong for systemic, vertically transmitted endophytes in grasses, as reproduction of these endophytes is closely linked with host survival and reproduction.[1] However, recent evidence suggests that even these endophytes have few protective effects against insects, perhaps because the cost of alkaloid defense outweighs the benefits to the host in most environments.

ENDOPHYTES AND PLANT DEFENSES

The term “endophyte” loosely refers to fungi that live asymptotically within plant tissues, although other microbes, such as bacteria and viruses, also inhabit plant tissues, and endophytic fungi may only be asymptomatic for part of their life cycle. Endophytic fungi are very abundant and often extremely diverse in both woody[2–4] and grass host plants (e.g., Ref. [5].) Curiously, endophytic fungi are the only plant-associated microorganisms that are postulated to directly increase host plant defenses against both vertebrate and invertebrate herbivores.[6,7] Endophytic fungi have been termed “acquired chemical defenses”[8] in grasses and “inducible defenses” and herbivore “antagonists” in woody plants.[6,9] Long-lived, slowly evolving plant hosts were thought to keep pace with rapidly evolving insect herbivores by allying with endophytic fungi and their mycotoxins.[6]

The main mechanism for increased plant resistance to insect herbivores is fungal production of mycotoxins. Endophytes may also alter plant physiology and morphology and thus increase resistance to stressful environments, competitive abilities, or uptake of limiting nutrients.[10] Endophytic mycotoxins, notably alkaloids, are now well documented for some systemic endophyte infections in pooid grasses, but relatively few mycotoxins have been isolated from the more diverse and localized infections in grasses and woody plants.[5]

Horizontally Transmitted Endophytes

The vast majority of fungal endophytes in plants, including grasses, form localized infections within plant tissues and are transmitted horizontally (from plant to plant) via hyphal fragments or spores, usually by wind or rainsplash. Sporulation implies that the asymptomatic nature is lost, and this usually occurs during senescence of plant tissue, when many of these fungal endophytes become saprophytic. Some endophytes in woody plants have been shown to increase host plant resistance to insect herbivores, especially sedentary insects, such as gall- ing insects.[11] Although originally proposed as plant defenses, most of this diverse group of microorganisms appear neutral, and even occasionally positive (e.g., Ref. [12]), in their interactions with insect herbivores.[2,3,5] An important caveat is that very few endophytes in relatively few host plants have been tested for resistance to insect herbivores. Nevertheless, the general lack of insect resistance due to these endophytes may not be surprising. Damage to plant tissues increases the likelihood of successful colonization of spores and hyphae. Therefore one would not expect endophytes to evolve to deter feeding, and thus damage, by insects through the production of mycotoxins. Furthermore, mobile insects may ingest hyphae and spores and transmit them via saliva or frass to colonization sites within or between host plants.[2] Although originally touted as a mechanism by which slowly evolving host plants enlist microbial partners to defend against rapidly evolving
insects, most horizontally transmitted endophytes appear to have few negative effects on invertebrate herbivores.\[^5\]

**Vertically Transmitted Endophytes**

Although far less diverse and less common than horizontally transmitted endophytes, seed-borne, systemic endophytes in cool-season, pooid grasses have nonetheless attracted much more attention for several reasons. First, the pooid grasses are economically important forage and turf grasses. Two agronomic grasses, tall fescue and perennial ryegrass, were introduced to North and South America and Australia and New Zealand from Eurasia, and now are the most widely cultivated grasses in North America, and are often infected by an asexual, vertically transmitted endophyte, *Neotyphodium*. Second, the systemic, seed-borne endophytes in pooid grasses were first known for their dramatic toxic effects on livestock, but later also on insect pests of grasses. Third, the mechanism of toxic effects, fungal production of alkaloids, is well established for the vertically transmitted endophytes in grasses. Systemic endophytes such as the asexual *Neotyphodium* and its sexual counterpart, *Epichloë*, produce a wide array of alkaloids in four major classes, and often at very high levels, depending on endophyte and host genotype and environmental factors, at least in some infected agronomic grasses. Some of these alkaloids, especially peramine, which is the most common alkaloid found in infected grasses, have deterrent and toxic effects on insect herbivores. However, deterrent effects of peramine on insects do not occur until concentrations are greater than 4 ppm dry mass, and many infected plants are often below these levels. Others, such as the ergot alkaloids, appear more effective against vertebrate herbivores. Fourth, evolutionary theory predicts that strictly vertically transmitted symbionts such as *Neotyphodium* should interact mutualistically with their hosts because the fitness of the symbiont is tightly linked to that of its host. Defense against herbivores via endophytic alkaloids is considered the primary vehicle for benefits to the host plant.

In general, systemic, vertically transmitted endophytes in agronomic grasses have negative effects on some, but not all, insect herbivores, root feeders, and seed predators of grasses.\[^5\] Most of these insects are introduced generalist pest species, such as aphids, Argentine stem weevil, fall armyworm, and sod webworm. Although relatively few have been studied, this generality does not appear to hold for systemic infections in native grasses. Despite earlier notions that most native grasses infected with vertically transmitted endophytes are toxic or deterrent to herbivores, recent evidence suggests the contrary.\[^{13,14}\] Instead, most native, cool-season grasses infected with seed-borne endophytes are not more resistant to either vertebrate or insect herbivores than their uninfected counterparts, and in some cases, less resistant.\[^{13}\] The contrast between marked negative effects of systemic endophytes in agronomic grasses and the relatively benign effects in native grasses is directly related to differences in alkaloid production. In native grasses, vertically transmitted endophytes produce fewer types and far lower and more variable levels of alkaloids than infected agronomic grasses, probably due to greater genetic diversity of host and endophyte, coupled with complex interactions with more variable environments.\[^{13,18}\]

Faeth\[^{13}\] listed several reasons why endophytes in native grasses do not generally form defensive mutualisms via alkaloids. First, nitrogen-rich alkaloids may be costly to produce and native grasses generally inhabit poorer nutrient environments than agricultural areas. Second, grasses generally tolerate grazing and herbivory rather than rely upon chemical defenses. Third, alkaloidal defenses may not be effective against specialized insect herbivores, which comprise the bulk of herbivorous insect species in natural communities. Fourth, herbivory in natural populations is generally more sporadic and less intense than agronomic pastures, and thus the cost of alkaloid production may outweigh any consistent benefits. Persistence of systemic endophytes in natural grass populations may be related to other potential benefits of endophyte infection, such as increased drought resistance, rather than fitness benefits related to resistance to insect or vertebrate herbivores. Alternatively, seed-borne endophytes may not be mutualistic at all, but rather persist in natural populations by several other mechanisms.\[^{16}\]

**CONCLUSION**

Although endophytes were originally envisioned as potent bodyguards of their hosts against insect herbivores, accumulating evidence suggests that the many endophytes do not have adverse effects on insects. Some endophytes, particularly those that are systemic, vertically transmitted in some agronomic grasses, do increase host plant resistance to herbivores through production of high levels of alkaloids. But these toxic endophytes represent the end of a continuum of endophyte interactions with host plants, ranging from parasitic to mutualistic, found in natural populations. There is growing recognition that mycotoxin-producing endophytes have great potential in crop and turfgrass improvement, especially in terms of resistance to pest insect species. In a larger sense, much of the basic ecology, evolution, physiology, and patterns of biodiversity of endophytes is still unknown.

INTRODUCTION

In the microbial world, bacteria feed on dead or living substrates to proliferate and survive. Some bacteria have evolved to become highly specialized in their feeding activities. Those that feed on living plants are pathogenic members of the gram-negative bacteria families Rhizobiaceae, Enterobacteriaceae, Pseudomonadaceae, Xanthomonadaceae, Ralstoniaceae, and Burkholderiaceae. Gram-positive pathogens are coryneform bacteria in the families Microbacteriaceae and Corynebacterineae. They form irregular rods and are non-spore formers. To recognize, infect, and consume plants, pathogenic species are equipped to sense and attach themselves to the host plant, invade and colonize host plant parts, secrete virulence effectors, and move into the intercellular spaces between cells or inside vessel elements. These processes culminate in disease symptoms. This article introduces the major types of disease symptoms caused by phytopathogenic bacteria. References for some specialized texts are provided for readers desiring more detailed information.

FOUR CLASSES OF DISEASE SYMPTOMS

Plant disease symptoms caused by pathogenic bacteria are classified into four general categories: 1) Overgrowths—non–self-limiting growths of plant tissues caused by cell enlargement (hypertrophy) and cell division (hyperplasia), resulting in excessive organ proliferation (fasciations) and/or undifferentiated tissue formation into tumors; 2) Rapid cell death (necrosis)—the rapid killing of cells caused by toxic proteins, effectors (e.g., hormones, proteases, kinases), and organic compounds produced by the invading pathogenic bacteria; 3) Generalized wilt—water stress of plant parts caused by blockage of vessel elements in the host due to exocellular polysaccharides, plant hormones, and other unidentified vessel occlusion factors elaborated by invading phytopathogenic bacteria; and 4) Soft-rot—maceration of plant tissue by invading bacteria that secrete powerful degradative enzymes capable of dissolving pectin (cell cementing material), cellulose, and complex proteins. In addition to these four types of symptoms, some plants become infected but remain symptomless. However, the pathogen isolated from these symptomless plants (which are often wild species,) can cause visible disease symptoms in cultivated species. Finally, there are plant diseases whose symptoms appear only after the crop is harvested and processed.

EXAMPLES OF EACH DISEASE TYPE

Overgrowths

Representative members of plant pathogenic bacteria that cause overgrowths can be found in the Rhizobiaceae, Enterobacteriaceae, Pseudomonadaceae, and Corynebacterineae families. Agrobacterium tumefaciens, a member of the Rhizobiaceae, causes a tumor disease called crown gall in a wide range of plant hosts when tested experimentally. In nature, crown gall occurs mainly on woody species such as peaches, plums, apricots, pears, cherries, almonds, walnuts, roses, brambles, kiwi, apples, and grapevines. Agrobacterium rhizogenes causes an interesting disease called hairy root, due to the abnormal proliferation of numerous roots from the site of infection. Besides root proliferation, fasciations in the form of leaf and flower proliferation into a witch’s broom (Fig. 1) can occur when plants are infected by Rhodococcus fascians. R. fascians harbors a linear plasmid that encodes a number of virulence effectors, such as isopentenyl adenosine monophosphate, a precursor of the cell growth hormone cytokinin. Olive knot, a tumor disease of olive trees and oleander shrubs, is caused by Pseudomonas syringae pv. savastanoi, a member of the Pseudomonadaceae (Fig. 2). Pantoea herbicola pv. gypsophilae is a member of the Enterobacteriaceae that causes galls on the ornamental baby’s breath plant, Gypsophila paniculata. P. herbicola pv. gypsophilae produces cytokinin during infection. [1]

Rapid Cell Death

Necrosis-producing bacteria are mainly represented in the Enterobacteriaceae, Pseudomonadaceae, and Xanthomonadaceae. Erwinia amylovora, a member of the...
Enterobacteriaceae and the causal agent of the fire blight disease of Rosaceae plants such as pears and apples, elaborates proteins, toxins, and virulence effectors that rapidly kill cells and assist in advancing the invading bacteria. The pathogen gains access into the host via blossoms and wounds. Necrosis of the blossom petiole followed by drooping of blackened leaves is typical of fire blight (Fig. 3). Pseudomonas syringae pv. syringae, a member of the Pseudomonadaceae that causes leaf blights on a wide range of plants and bacterial canker of peaches.

and other *Prunus* species, produces peptide toxins (e.g., syringomycin), polysaccharides, plant hormones, and at least 11 virulence effector proteins during tissue colonization. The effectors cause cell death by altering the movement of ions across cell membranes, initiating water leakage from within cells (which temporarily fills intercellular spaces, resulting in a symptom called water-soaking), and by altering normal cellular processing mechanisms. *Xanthomonas axonopodis* pv. *citri*, a member of Xanthomonadaceae, causes citrus canker whose

**Fig. 3** Fire blight of pear caused by *Erwinia amylovora*. The scorched appearance of the foliage is typical of the disease.

**Fig. 4** Citrus canker of young fruit caused by *Xanthomonas axonopodis* pv. *citri*. (Photo courtesy of Dr. Dean Gabriel, University of Florida, Gainesville.)
symptoms are typified by raised pustulelike or blisterlike lesions on fruits and leaves. Lesions appear about 7 to 14 days after inoculation followed by the formation of craterlike spots lined with tan-colored tissue. An oily water-soaked margin accompanied by a yellow halo occurs around the spots. On fruit, the blisterlike lesions are pronounced (Fig. 4). Another member of the Xanthomonadaceae is *X. campestris* pv. malvacearum, the causal agent of angular leaf spot of cotton (Fig. 5). The many lesions on the leaf enlarge and coalesce into angular regions, and leaves later drop off prematurely. *X. campestris* pv. dieffenbachiae causes leaf spots on *Anthirium* species (Fig. 6), from where the pathogen prolifically invades the vascular system, in which massive amounts of ooze are produced (Fig. 7).

**Generalized Wilt**

Vascular wilt-inducing bacteria are as economically important as necrogenic pathogens. *Clavibacter michiganense* subspecies, which are non–spore-forming, gram-positive members of the Microbacteriaceae, cause wilt diseases of specific plants. For example, *C. michiganense* subsp. *michiganensis* causes a wilt disease of tomato plants called bacterial canker. The wilt symptoms are followed by tissue necrosis producing scorched-appearing foliage, cankers (depressions in the stem caused by
death of tissue beneath the epidermis), killing of the pith, and spots on the fruit. Another member of this gram-positive group is *C. michiganense* subsp. *insidiosus*, which causes a wilt disease of alfalfa. Infected alfalfa plants are often severely stunted (Fig. 8). *Ralstonia solanacearum*, the sole plant pathogenic member of the family *Ralstoniaceae*, causes wilt disease of at least 30 plant families. Plants of the Solanaceae family such as potato, tomato, eggplant, and bell pepper are very susceptible to *R. solanacearum* strains classified as Race 1. *R. solanacearum* strains of Race 2 infect banana and cooking banana, causing Moko and Bugtok diseases, respectively (Fig. 9). *Erwinia salicis*, a member of the Enterobacteriaceae, causes wilt of the cricket bat willow tree through vessel occlusion, which is followed by necrosis of the vascular cylinder.

**Soft-Rot**

Bacteria that cause tissue dissolution resulting in soft rot are mainly members of the Enterobacteriaceae and Pseudomonadaceae. A prototypical example of the Enterobacteriaceae is *Erwinia carotovora* subsp. *carotovora*, a relatively fast growing, rod-shaped bacterium that initiates infection through wounds. Infection progresses as the pathogen elaborates a number of enzymes that break down pectin into consumable oligosaccharides, as well as cell wall material and proteins into utilizable substrates. *E. carotovora* subsp. *carotovora* infects tubers, roots, and corms. The organism also causes the blackleg disease of potato, typified by the rapid collapse of the potato plant in the field (Fig. 10). A member of the Burkholderiaceae, *Burkholderia cepacia* is a complex species that is currently divided into genomovars (genetic species) I, III, and VI. Plant pathogenic strains in genomovar I cause a soft rot of onion bulbs called sour skin disease. Like other soft-rot pathogens, *B. cepacia* produces a number of enzymes and virulence effectors that facilitate dissolution of the onion bulb tissues (Fig. 11). Certain strains of *B. cepacia* are used as biocontrol agents, whereas other strains are opportunistic human pathogens that infect individuals with cystic fibrosis.[2]

**SYMPTOMLESS DISEASES**

Besides the four basic plant disease symptoms, some bacterial diseases do not produce symptoms in the field. For example, the economically important pink disease of pineapple becomes apparent only when the fruit is canned. Pink disease is caused by *Pantoea citrea*, a member of the Enterobacteriaceae that infects the fruit via the florets and produces enzymes that oxidize glucose into ketogluconates, which upon heating results in the

---

*Fig. 7* Ooze from *Anthirium* stem systemically infected by *Xanthomonas campestris* pv. dieffenbachiæ.
formation of a red pigment that stains the canned pineapple fruit, resulting in an unmarketable product \cite{3,4} (Fig. 12).

*Xylella fastidiosa*, a member of the Xantomonadaeae, remains latent in a large number of symptom-free wild plants such as California blackberry, Russian thistle, Creek Nettle, Sudan grass, and at least 36 distinct plant species, including wild grape (*Vitis californica* Benth.).\cite{5} When experimentally inoculated with *X. fastidiosa*, these plants remain symptomless, yet remain as carriers of the pathogen.\cite{5} Asymptomatic wild plant species apparently tolerate the pathogen, even though their xylem is filled with the bacterium. Hence, these wild plants serve as the reservoir of *X. fastidiosa*. In contrast, cultivated plants when infected by *X. fastidiosa* develop severe leaf symptoms such as marginal scorched (Fig. 13) and fruit wilt (raisining) (Fig. 14). *X. fastidiosa* is transmitted from diseased and symptomless plants to crops by the waxy-winged and sharpshooter leaf hoppers. Pierce’s disease of grapevines, leaf scorch of almond and plum trees, and variegated chlorosis of citrus are some of the diseases caused by *X. fastidiosa*. *Clavibacter xyli* subsp. *xyli* (now called *Leifsonia xyli* subsp. *xyli* by some researchers) causes ratoon stunting disease of sugarcane. The disease is difficult to diagnose, because modern commercial varieties of sugarcane usually exhibit no external symptoms of infection. Producers may not know they have a problem until yields come in below expectations. Even though older varieties of sugarcane may show reduced vigor (stunting), this symptom is

CONCLUSION

Overgrowths, rapid necrosis, generalized wilt, and soft rot are four distinct symptom classes of plant diseases caused by plant pathogenic bacteria. Each type of symptom reflects the specific type of infecting bacterial species. Overgrowth or tumor-inducing bacteria are generally equipped to elaborate phytohormones. Necrogenic bacteria are known to inject an array of toxic peptides and virulence effectors. Wilt-causing bacteria invade and proliferate in the vascular elements, interrupting fluid transport in the plant. Soft-rot–causing bacteria elaborate a series of degradative enzymes that hydrolyze pectin, cell wall components, and complex proteins. All plant pathogenic bacteria infect their respective plant hosts to create a niche for competitive survival and perpetuation in nature. The host generally provides the food substrates for bacterial survival. In this article, broad examples of diseases caused by plant pathogenic bacteria were provided. Also, examples of asymptomatic diseases are addressed and represent a significant area. Here, native, symptom-free plants are not harmed by the latently infecting bacteria, but modern day, genetically-altered crops are highly susceptible to the same plant pathogenic bacteria that resides in asymptomatic wild species. It appears, therefore, that crop breeding programs have reduced natural resistance to various pathogenic effectors of the plant pathogen.

Plant Diseases Caused by Phytoplasmas

Elisabeth Boudon-Padieu
Institut National de la Recherche Agronomique, Centre de Recherches de Dijon, Dijon, France

INTRODUCTION

Plant diseases caused by phytoplasmas were first described as “virus-like” yellow diseases because symptoms could be induced in healthy plants after grafting with shoots from affected plants, or by insect transmission. However, there was no evidence of the putative viruses. Plant yellow diseases share common symptoms that include leaf yellowing, virescence or phyllody of flowers, absence or anomalies of fruit, and decline or dieback. In 1967, these diseases were associated with organisms observed in thin sections of phloem tissues from dwarfed mulberry plants. The organisms resembled a class of prokaryotic animal pathogens called mycoplasmas, and hence were named mycoplasma-like organisms (MLOs). Subsequently, they have come to be known as phytoplasmas. Unlike mycoplasmas, phytoplasmas have not been cultured in vitro. However, with the development of serological and molecular assays, knowledge on the etiology and epidemiology of phytoplasma diseases has greatly improved.

BIOLOGY OF PHYTOPLASMAS

First assumed to be unknown viruses,[1] then called mycoplasma-like organisms,[2,3] phytoplasmas[4] are obligate, intracellular, parasitic, wall-less bacteria that are transmitted by phloem-feeding insect vectors and by grafting. They are heterogeneous in size and polymorphous, appearing in infected plant tissues and insect vectors as round bodies 50–1000 nm in diameter.[2,5,6] In the plant, they occupy only phloem sieve tubes and are distributed to all organs.[5] However, their distribution is uneven, and their movement and multiplication are not fully understood. Phytoplasmas persist over the winter in dormant wood and in roots. Phytoplasmas multiply and persist in the bodies of vector insects, especially in the gut wall cells and secretory cells of salivary glands.[6] However, because they are not transmitted to the progeny, plant hosts are essential for the survival of phytoplasmas.

CLASSIFICATION OF PHYTOPLASMAS

Because they have not been grown in vitro, phytoplasmas have long remained mysterious organisms with unknown phylogenetic characters. Numerous strains of phytoplasmas have been transmitted by grafting, insect feeding, or infection by parasitic higher plants (i.e., dodders). The bacteria have been maintained by subgrafting under greenhouse conditions. In the 1980s and 1990s, serological and DNA-based assays were developed to better understand the geographical distribution and phylogeny of these pathogens. Phytoplasmas have a small genome size, ranging from 500 to 2200 kb.[6] By analyzing the 16S rRNA gene, more than 200 phytoplasmas have been grouped within the class Mollicutes, in a homogeneous clade that contains about 20 groups and subgroups, distinct from other Mollicutes.[4] Data obtained by sequence analysis of other rDNA regions support such classification. Additionally, data on serological relationships confirm ribosomal grouping. Biological traits such as natural host range and pathogenicity do not clearly agree with the groupings established by molecular data.

PLANTS AFFECTED BY PHYTOPLASMAS

Phytoplasmas have been reported only from angiosperms. They have been detected in hundreds of plant species in numerous families in all continents.[3,4] Although phytoplasmas were described as plant pathogens, numerous plants can be symptomless when infected. This is of particular importance with weed species that can be discrete reservoirs. Phytoplasma diseases severely affect numerous crops, and their economic importance can be very high because infected plants cannot be cured.

SYMPTOMS ASSOCIATED WITH PHYTOPLASMA INFECTION

Phytoplasma infection alters the formation and development of flowers, fruits, seeds, tubers, and roots. It is also associated with the decline of grapevines, fruits, forest trees, and shrubs. Sometimes, similar symptoms develop on plants of the same species infected with different phytoplasmas. For example, grapevine yellows, which occur in four continents and show similar symptoms, have been associated with at least five different phytoplasmas.[7] Similarly, symptoms of stolbur on tomatoes (i.e.,
hypertrophied calyxes containing virescent stamina, petals, and pistils, together with yellowing or reddening and epinasty of leaves) in Europe, South America, and Australia have been associated with four different phytoplasmas. Plants of Catharanthus roseus, a species widely used to maintain phytoplasmas by subgrafting, display a variety of symptoms when infected with different phytoplasmas, including severe decline vs. active growth of stems with short internodes or proliferation of axillary buds into witches’ brooms and development of small flowers vs. virescence and phyllody.

INSECT VECTORS OF PHYTOPLASMAS

All insect vectors of phytoplasmas belong to families in the order Hemiptera. However, only a limited number of vector species are known among leafhoppers (Cicadellidae), planthoppers (Fulgoroidea), and psyllids (Psyllidae). Vector transmission can be very specific when the insect species is a monophage or oligophage. Only psyllids are known as vectors of fruit tree phytoplasmas that belong to the apple proliferation group, whereas several insect species are vectors of phytoplasmas of the larger group of aster yellows. Flavescence dorée (FD), a phytoplasma that attacks grapevines, is exclusively transmitted by the vine-feeding leafhopper Scaphoideus titanus Ball. Alternatively, insects belonging to the same family can be vectors of the same or closely related phytoplasmas. At least three planthoppers in the Cixiidae family have been shown to be vectors of phytoplasmas of the stolbur group, which are ubiquitous pathogens of numerous crops and weeds in Europe and Australia. Altogether, a long-lasting coevolution of phytoplasmas with their insect vectors could account for their intimate and complex relationships.

INSECT TRANSMISSION

Phytoplasmas are transmitted by insect vectors in the persistent mode, with a latency between feeding acquisition and the moment when insects are infective (i.e., able to inoculate healthy plants). As an example, a latency of 4–5 weeks is required in the case of FD phytoplasma transmitted by the natural vector S. titanus or by an experimental vector Euscelidius variegatus. Leafhoppers are then infective for the rest of their life, but they do not pass phytoplasmas to their progeny. Transmission cycles of phytoplasmas are complex systems that depend on the biology of plant and insect hosts, and demonstrate some plasticity under different environmental conditions. As indicated above, plant hosts are essential for the survival of phytoplasmas. Phytoplasmas transmitted by a unique vector species with one generation a year and a limited period of activity require at least one perennial host plant as an overwintering reservoir. Phytoplasmas transmitted by a species with one generation a year and instars developing throughout the year, or by a species that undertakes several generations a year, can persist both in insects after acquisition (larval instars or adults of the winter generation) and in plant hosts. Ubiquitous phytoplasmas are transmitted by one or several polyphagous insect species to several cultivated and wild plants. The basis for vector specificity is not known and might prove essential in preventing the dissemination of phytoplasma diseases.

DISSEMINATION OF PHYTOPLASMAS

The feeding activity of insect vectors is responsible for the short-range dissemination of phytoplasmas. Hence the incidence of a disease in a crop is related to the proportion of infective insects within the vector population. Conversely, long-distance spread occurs when the phytoplasma, the susceptible host, and the insect vector meet in a new region. Resident insect species might prove to be efficient vectors of an exotic phytoplasma, or an exotic vector species may transmit a local phytoplasma. Hence, the appearance of a disease in a new area may result either from the introduction of a phytoplasma source with infected planting material and/or the introduction of a potential insect vector species.

MANAGEMENT OF PHYTOPLASMA DISEASES

Primary control of phytoplasmas relies on exclusion and prophylaxis. Care should be taken to avoid introducing infected germplasm into new regions. Because there is no evidence for seed transmission of phytoplasmas, efforts should be focused on ensuring phytoplasma-free vegetative planting material. Fully dormant lignified propagation materials suspected of infection can be disinfected by soaking in water at 50°C for 45 min. The introduction of exotic insect species should also be avoided. Control measures for an established disease require knowledge of the biology of insect vector and other inoculum sources. When vector refuges are known, control of the species can be achieved with targeted spraying of insecticides or with destruction of host plants. Similarly, destruction of phytoplasma reservoirs is recommended to lower the
inoculum pressure. In perennial crops, removal of infected trees is recommended when the disease pressure is high (i.e., in epidemic phase). Pruning of affected parts of the tree may limit crop loss; however, it does not control the spread of the disease if vectors are not controlled at the same time. Cases of natural recovery of woody plants are known, but this mechanism has not been elucidated. Natural recovery could be used to return to a satisfactory sanitary status when the disease pressure is not too high, provided that insect vectors are controlled during and after the recovery process. Phytoplasmas, lacking a cell wall, are sensitive to tetracycline. However, this antibiotic is bacteriostatic rather than bacteriocidal. Injection of trees are sensitive to tetracycline. However, this antibiotic is bacteriostatic rather than bacteriocidal. Injection of trees may be efficient but not durable, and it would be detrimental to the environment and result in the selection of antibiotic-resistant pathogens. Finally, cross-protection and induced resistance, which are partial resistance induced by a primary infection with another pathogen or with an attenuated strain of the same pathogen, have been reported, but more research must be performed in the latter fields.

**FUTURE PROSPECTS**

Numerous reports in the past 10 years indicate that the incidence of known diseases associated with phytoplasmas is increasing. Research on phytoplasma–host interactions should yield effective strategies for managing these diseases. Of particular interest are interactions with insect organs at the cellular level and plant resistance response mechanisms. The introduction of plant resistance to vector feeding or phytoplasma multiplication is a long-term objective. Additionally, a search for natural enemies of insect vector species could also lower the incidence of these diseases to an acceptable level.

**CONCLUSION**

Phytoplasmas have long remained mysterious plant pathogens. In the last decade, important information has been obtained on their biology, transmission, vectors and host plants. However, new plant diseases associated with phytoplasmas are being described in all continents, probably due to extending rate of exchange between distant countries and more and more frequent introduction of exotic plant germplasm and pests in new areas. More knowledge is needed on the origin of phytoplasmas and on environmental factors which contribute to the emergence of new diseases.

Plant Diseases Caused by Subviral Agents

Peter Palukaitis
Scottish Crop Research Institute, Invergowrie, U.K.

INTRODUCTION

Plant diseases also can be caused by other viral-like pathogens referred to collectively as subviral agents. These include replicating small RNAs without genes, known as viroids, and other subviral pathogens known as satellites, which require helper viruses for parts of their life cycle. The latter include satellite viruses, which encode their own coat protein but depend on another virus for their replication and movement, and satellite RNAs and DNAs, which depend on another virus for all of these functions. Satellites can modify the diseases induced by their helper viruses.

VIROIDS AND DISEASES CAUSED BY VIROIDS

Viroids were first described conceptually in the early 1970s, although the diseases that many caused were known for most of the century.\(^1\)\(^,\)\(^4\) Viroids are naked, highly structured RNAs of small size (245–401 nucleotides), which do not encode proteins and thus depend on polymerases encoded by their host plants for their replication. They appear to contain the ability to move throughout their host plants.\(^4\) At present, there are 28 viroid species\(^2\)\(^,\)\(^4\) (Table 1). The two families of viroids (Agsunviroidae and Pospiviroidae) show differences in structure, conserved sequences, and ability to undergo autocatalytic cleavage, via ribozymes.\(^2\)\(^,\)\(^4\) These physical differences also correlate with their sites of replication; i.e., the viroids in the Amsunviroidae are replicated by a polymerase in chloroplasts, and at least some viroids in the Pospiviroidae have been shown to be replicated by a nuclear RNA polymerase.\(^4\)

Viroids have been found to be the causal agents of a number of plant diseases, primarily in tropical zones, and to a lesser extent in temperate zones.\(^1\)\(^,\)\(^4\) The major diseases caused by viroids include the spindle tuber disease of potatoes, the sunblotch disease of avocados, various diseases of citrus, cucumber grapevine, hops, pear, and apple, and a number of diseases of ornamental plants\(^4\) (Table 1). However, the most devastating disease caused by viroids is the decline observed in coconut palm in the Philippines. It is estimated that about 40 million trees here have been lost due to this disease, known locally as ‘cadang-cadang.’\(^4\) The mechanisms by which viroids induce disease are not known, although it is believed that they alter developmental processes in their host plants, as well as activate disease response genes.\(^4\) In various crop species, the control of the spread of viroids has been accomplished by a combination of removing infected materials, cleaning up breeding lines (through either meristem tip culture coupled with thermotherapy, or by obtaining new sources of disease-free germplasm), and other rigorous phytosanitary measures, especially for orchard plants.\(^4\) This has led to the control of a number of viroid diseases in Australia, Europe, and North America.

SATELLITES AND DISEASES CAUSED BY SATELLITES

In contrast to viroids, which are not encapsidated into particles, satellites depend upon “helper viruses” either for their replication as well as encapsidation into the particles of their helper virus (satellite RNAs and satellite DNAs), or for their replication alone, as they encode and are encapsidated by their own coat proteins (satellite viruses).\(^1\)\(^,\)\(^3\) Satellites differ from defective RNAs and subgenomic RNAs of plant viruses in not having extensive nucleotide sequence identity with their helper virus.\(^3\)\(^,\)\(^5\) There are only four known satellite viruses (Table 2). Except for Panicum mosaic satellite virus, which intensifies the disease elicited by its helper virus satellite viruses, the other satellite viruses do not significantly affect the diseases caused by their respective helper viruses. Thus far, there are six definitive satellite DNAs (Table 2), but there more being characterized.\(^3\) Satellite DNAs all contain singlestranded DNA genomes and all are associated with singlestranded, circular, DNA viruses (geminiviruses). Except for the satellite DNA of tomato leaf curl virus, which contains 682 nucleotides, the other satellite DNAs all contain about 1300 nucleotides.

By contrast, there is considerably more variation in type, size, number, and helper viruses among the satellite RNAs. These are grouped on the basis of whether they encode proteins (large satellite RNAs) or do not do so, and are either linear molecules (small linear satellite RNAs) or form circular molecules (circular satellite RNAs), at least
at some stage in their replication cycle\textsuperscript{[3,5]} (Table 2). The large satellite RNAs vary in size from about 800–1500 nucleotides. Some encode proteins required for their replication, while others do not. The small linear satellite RNAs contain about 300–900 nucleotides and the circular satellite RNAs are 220–457 nucleotides\textsuperscript{[3–5]} In a number of cases, members of these various classes of satellite RNA have the ability to alter the diseases induced by their helper viruses. In some cases, the satellite RNAs intensify such disease, while in other cases, they may attenuate the virus-induced disease\textsuperscript{[5]} In the case of some satellite RNAs, different variants can attenuate symptoms or exacerbate the disease induced by the helper virus, and in one case, the same satellite RNA species can intensify symptoms on one host and attenuate symptoms on another host\textsuperscript{[5]} The small, circular, satellite RNAs have sizes and structures similar to that of a number of viroids\textsuperscript{[4,6]} In common with some of these viroids, these satellite RNAs replicate through a rolling circle mechanism, generating multimeric copies of these RNA molecules. These multimeric copies may or may not be encapsidated by the helper virus\textsuperscript{[4]} The major satellite RNA molecules present in the cell and inside virus particles are of the monomer species, processed and circularized via ribozymes.

### RIBOZYMES: AUTOCATALYTIC RNA

Ribozymes, or RNA enzymes, are RNA sequences that fold into particular structures, allowing them to cleave and/or ligate RNA molecules. A number of these have been found associated with viroids in the family Avsunviroidae, and with the circular satellite RNA\textsuperscript{[1,4–7]} The ribozymes associated with subviral agents are classified into two types of autocatalytic structures called hammerhead ribozymes and hairpin ribozymes\textsuperscript{[7]} These have been studied quite extensively in recent years, in order to understand their mechanisms of cleavage. Various applications for the use of these ribozymes have been suggested, including in molecular medicine\textsuperscript{[8,9]}

### CONCLUSION

Viroids and satellites have provided some valuable tools in our understanding of basic molecular processes, and in furthering our knowledge about pathogenic agents and the roles of RNAs in pathogenicity. More of these agents are being discovered each year, and these pathogens are being recognized as the etiological agents of either new or previously unclassified diseases\textsuperscript{[1–4]} There is a web site available that contains the nucleotide sequences of all of the known isolates of viroids and satellite RNAs, as well as the secondary structure of these agents. This site also provides information on the presence and structure of any ribozymes associated with such RNAs, as well as the secondary structure of these agents. This site also provides information on the presence and structure of any ribozymes associated with such RNAs.\textsuperscript{[6]} Although considerable work has gone into modifying viroids or satellite RNAs for agricultural applications, most of these efforts have not as yet yielded any success. On the other hand, one satellite virus has been modified successfully to express additional RNA sequences in plants, resulting in suppression of the expression of target genes by the RNA silencing pathway.\textsuperscript{[10]} The discovery of ribozymes in several subviral agents has generated considerable interest, although applications of this technology to...

Plant DNA Virus Diseases

Robert L. Gilbertson
Maria R. Rojas
University of California, Davis, California, U.S.A.

INTRODUCTION

The majority of plant virus diseases are caused by viruses with single-stranded RNA genomes. Three families of plant viruses have DNA genomes, and some DNA viruses cause economically important diseases, particularly in tropical and subtropical regions. Members of the family Caulimoviridae have a circular double-stranded (ds) DNA genome. The type member, Cauliflower mosaic virus (CaMV), is the source of the 35S promoter, which is widely used in plant biotechnology. Banana streak and rice tungro are important diseases caused by caulimoviruses. Members of the family Geminiviridae have a circular single-stranded (ss) DNA genome and distinctive twinned icosahedral virions. The whitefly-transmitted geminiviruses (genus Begomovirus) have emerged as one of the most economically important groups of plant viruses. Geminiviruses cause devastating diseases such as African cassava mosaic, bean golden mosaic, beet curly top, cotton leaf curl, maize streak, and tomato yellow leaf curl. Viruses in the family Circoviridae have a multipartite circular ssDNA genome and distinctive nanoviruses cause plant diseases. Banana bunchy top virus is the type species of the genus Caulimovirus. The genome of these viruses is composed of a single circular dsDNA (approximately 8.0 kilobase (kb) pair), which is encapsidated in isometric (spherical) particles approximately 50 nm in diameter. Caulimoviruses cause mosaic-type diseases (mosaic, mottle, ringspots, and malformation in leaves and stunted plant growth) of dicot crop, ornamental, and weed plants; examples include cauliflower mosaic, carnation-etched ring, dahlia mosaic, and strawberry vein banding. Caulimoviruses have narrow host ranges and are spread, plant-to-plant, by aphids or via propagative material, but not through seed.

BADNAVIRUSES: BACILLIFORM dsDNA VIRUSES CAUSING BANANA STREAK AND RICE TUNGRO DISEASES

In the late 1980s, a new type of DNA virus was identified with a circular dsDNA genome of approximately 7.5 kb, and bacilliform (bullet)-shaped virions (100–300 × 30 nm). These viruses were placed into the genus Badnavirus (ba [bacilliform]-dna [DNA]-virus) in the family Caulimoviridae (Table 1). Badnaviruses cause diseases including banana streak, rice tungro, and cacao swollen shoot (Table 2). Banana streak is a mealybug-transmitted disease found in many banana growing regions. In addition to causing losses due to reduced size and production of banana fruit, the dsDNA genome of Banana streak virus (BSV) can become integrated into the banana genome, complicating the production of BSV-free propagative material. Rice tungro is a devastating disease of rice in certain areas of Asia, and its impact was particularly severe on high-yielding rice varieties introduced during the green revolution. The disease is caused by a complex of two viruses: Rice tungro bacilliform virus (badnavirus) and Rice tungro spherical virus (ssRNA virus), and is spread by leafhoppers. The development of rice varieties resistant to the insect vector has been an effective management tool in certain areas (Table 2). Cacao swollen shoot is a mealybug-transmitted disease of considerable importance in West Africa and Sri Lanka, where it reduces yield and quality of cacao by inducing swelling and necrosis of stems and roots.

GEMINIVIRUSES: THE FIRST SINGLE-STRANDED DNA VIRUSES SHOWN TO CAUSE DISEASES IN PLANTS

Viruses in the family Geminiviridae have circular ssDNA genomes (3.0–5.5 kb) encapsidated in small (18 × 30 nm) twinned icosahedral virions.[3,6,7] The family name comes from the distinctive virion shape and from the Latin word “geminus,” meaning twin. Plant diseases caused by geminiviruses were recognized long before the nature of the causal agent was determined, and the first recorded observation of a plant disease—an aesthetically pleasing yellow vein symptom described in a Japanese poem in 752 A.D.—may have been caused by a geminivirus.[3,6] Today, the yellow variegation (mosaic) of the ornamental

(View this art in color at www.dekker.com.)
flowering maple (*Abutilon spp.*) is due to infection by the geminivirus *Abutilon mosaic virus* (Fig. 1A).

In the late 1970s, geminiviruses were identified and characterized and shown to be the causal agents of many important diseases, including African cassava mosaic, maize streak, and bean golden mosaic (Fig. 1). Geminiviruses have been classified into four genera based on the insect vector, host range, and genome structure (Table 1) and are among the most economically important plant viruses.

**GEMINIVIRUS DISEASES HAVE EMERGED AS MAJOR THREATS TO CROP PRODUCTION**

Geminiviruses cause many important diseases (Table 2, Fig. 1). In southern Africa, India, and islands in the Indian Ocean, maize streak is the most damaging viral disease of maize, causing streaking of leaves, stunted growth, and reduced yields (Fig. 1C). The development of moderately resistant varieties has helped reduce losses due to this leafhopper-vectored mastrevirus. Curly top disease is caused by three curtovirus species vectored by the beet leafhopper (*Circulifer tenellus*) (Table 1). Disease symptoms include twisted, crumpled, and yellowed leaves; stunted and distorted growth; and vascular discoloration (Fig. 1E). The disease occurs in the western United States, certain Mediterranean countries, and South America. In the early 1900s, curly top nearly destroyed the sugar beet industry in the United States until resistant varieties were developed. The disease still causes losses in tomato and other crops in the U.S. State of California, and an annual spray program is used in an attempt to control the disease by reducing populations of the leafhopper vector.

Diseases caused by whitefly-transmitted geminiviruses (genus *Begomovirus*) (Table 1) have emerged as major constraints on vegetable and field crop production in tropical and subtropical regions throughout the world (Table 2). This is due to a worldwide increase in the population and distribution of whiteflies (*Bemisia* spp.) and monoculture of susceptible crops in areas with indigenous weed-infecting geminiviruses. Diseases caused by begomoviruses are characterized by mosaic/mottle, curling, crumpling, and/or yellowing of leaves; stunted and distorted growth; and a reduction in yield quantity and quality (Fig. 1). African cassava mosaic is a devastating disease in many countries of Africa, causing significant yield losses (e.g., approximately 50% of total production) (Table 2, Fig. 1B). In the late 1990s new, highly pathogenic forms of *African cassava mosaic virus* appeared, arising by genetic recombination. They have caused even greater losses. Bean golden mosaic (Fig. 1D) causes significant losses (as high as 100%) to common bean production in South and Central America and Mexico, and management options remain limited. Some bean varieties possess moderate resistance, but one of the most effective strategies has been a bean-free period of 2–3 months (Table 2). Cotton leaf curl has devastated cotton production in some parts of Pakistan and India, and is caused by a complex of a begomovirus and a nanovirus-like satellite DNA (Table 2).

**BANANA BUNCHY TOP DISEASE: AN ECONOMICALLY IMPORTANT DISEASE CAUSED BY A NANOVIRUS**

Banana bunchy top disease (BBTD) is the most important viral disease of banana. First described in the South Pacific in the late 1800s, the disease spread to Australia, Africa, India, the Philippines, and Sri Lanka. BBTD is characterized by the bunchy appearance of the upper portion of the plant, narrow and dwarfed leaves, and dark green streaks on leaves and stems. Infected plants become severely stunted and yield losses can reach 100%. The disease is transmitted by aphids and via propagative materials. Originally thought to be caused by a luteovirus,
BBTD was subsequently shown to be caused by a spherical virus with a multipartite circular ssDNA genome. The virus was named *Banana bunchy top virus* (BBTV). Effective management of BBTD involves the use of quarantines, virus-free propagative material, and a strict regime of sanitation and eradication of diseased plants (Table 2). This approach has been highly effective in Australia, but less effective in other areas. Other diseases caused by viruses similar to BBTV include faba bean necrotic yellows, coconut foliar decay, and subterranean clover stunt. These viruses have been placed into the genus *Nanovirus* in the family Circoviridae (Table 1).

**CONCLUSION**

Although DNA viruses represent a minority of the total viruses that infect plants, they cause many economically important plant diseases, particularly in tropical and subtropical regions. Management of these diseases has been difficult and successful cases have always involved an integrated regional approach that is based on a thorough understanding of viral biology and disease epidemiology.

**REFERENCES**

INTRODUCTION

All plant pathogens cause disease on a restricted range of plant species but the extent of host specificity differs considerably, presumably as a consequence of different sorts of evolutionary trade-off. The driving force in the evolution of plant–pathogen interactions is conceived as an “arms race” between defense and pathogenesis with the ability to cause diseases of plants almost certainly originating several times during evolution. Two distinct evolutionary routes are likely: 1) acquisition of the capacity to invade living plant tissues by saprotrophic organisms formerly deriving nutrition from dead plant material, and 2) acquisition of pathogenic traits by organisms involved in previously established mutualistic symbioses. Organisms pathogenic on plants may derive their nutrition by either biotrophic or necrotrophic processes. The former involves an intimate association with living cells, and the capacity to stop them dying, while the latter involves the capacity to kill cells, sometimes without direct contact.

DISCUSSION

Co-evolution can be conceived as a process whereby components of non-host resistance are sequentially assembled in evolutionary time and give rise to the degree of host specificity observed in present-day host–pathogen associations. The suggestion is that the diversity of these defenses parallels the evolution of plant species and the pathogens to which they are accessible. An alternative hypothesis is that all plant cells have the capacity to recognize non-self and to actively elaborate a defense response. In this hypothesis, it is envisaged that the defense response of all plants is essentially similar except for subtle variations on the theme; host specificity and the process of co-evolution reside in the recognition process. It is known that micro-evolutionary change over short time periods is mediated by a gene-for-gene relationship involving the recognition of pathogen derived molecules for which within-taxa variation occurs. It is envisaged that recognition events mediating non-host resistance could involve taxon-specific molecules that are invariant and biologically essential to the potential pathogen. Consequently, genotype-specific interactions between host plants and their pathogens mediated by gene-for-gene recognition may simply represent the “tip of an iceberg” in this type of surveillance and response based defense. Recognition specificity may be contributed primarily, but not exclusively, by a leucine-rich repeat domain (LRR) common to the proteins encoded by different classes of plant resistance (R) gene. This domain comprises a variable number of repeats of the motif xxLxLxx (where L is a conserved aliphatic residue, leucine or isoleucine) putatively providing an array of solvent-exposed ligand-binding surfaces. For several R gene families, regions of the LRR have been shown to be under diversifying selection as indicated by a ratio of greater than one for the synonymous to non-synonymous substitutions of the nucleotides encoding residues in the region. The way in which the molecular machinery for signal recognition and transduction is assembled within and between individual plants may be subject to combinatorial variation. Such variation may allow individual plants to recognize and respond effectively to molecules that represent the invariant signature of potential pathogens to which the plant is a non-host. At the same time, the system can provide access to the necessary genetic variation to facilitate a micro-evolutionary response to the tiny sub-set of pathogens of the host species that are detected only by genotypically variant molecular cues on which selection acts to enhance pathogen success.

EVOLUTION AS AN “ARMS RACE”

Plants are intrinsically resistant to the vast majority of agents known to have pathogenic competence. Despite the constant assault on aerial and subterranean plant organs by potential pathogens, most plants are healthy; this healthy state is a consequence of effective defense mechanisms. The driving force in the evolution of plant-pathogen interactions is therefore an “arms-race” between defense and pathogenesis. This “arms-race” commenced before plants colonized land, and certain proteins involved in the mediation of defense against microbial pathogens by both vertebrate and invertebrate animals, as well as plants,
share structural homology\textsuperscript{[1,2]} that may represent conservation of function dating from before divergence of the plant and animal kingdoms.

**EVOLUTIONARY ROUTES TO ESTABLISHMENT OF PATHOGENIC INTERACTIONS WITH PLANTS**

The ability to cause diseases of plants undoubtedly originated several times during evolution given the phylogenetic diversity of present-day plant pathogens. However, despite this polyphyletic origin there are likely to have been two distinct routes to the establishment of plant pathogenesis: 1) acquisition of the capacity to invade living plant tissues by saprotrophic organisms formerly deriving nutrition from dead plant material, and 2) acquisition of pathogenic traits by organisms involved in previously established mutualistic symbioses. There is evidence for both bacteria and fungi that horizontal transfer of blocks of genes ("pathogenicity islands") has contributed to the evolution of plant pathogenic capability.

**MODES OF NUTRITION AND HOST SPECIFICITY**

Two other general observations about the diversity of present-day plant–pathogen interactions are relevant to consideration of their evolutionary origins: mode of nutrition and host specificity. Organisms pathogenic on plants may derive their nutrition by either biotrophic or necrotrophic processes. The former involves an intimate association with living cells and the capacity to stop them dying, while the latter involves the capacity to kill cells, sometimes without direct contact.

All plant pathogens cause disease on a restricted range of plant species but the extent of host specificity differs considerably, presumably as a consequence of different sorts of evolutionary trade-off. For example, there may be trade-off between a pathogen’s host range, its capacity to kill plant tissues, its capacity to persist and reproduce on any particular host, and its mode of transmission between hosts. In diverse ecosystems (unlike agriculture) propagules of a pathogen with a wide host range will more readily make contact with a new susceptible host than will a pathogen with a restricted host range. However, pathogen reproductive success will not necessarily always be correlated with wide host range or host mortality. Based on observation of existing host–pathogen associations, it frequently appears to be the case that co-evolution results in an increasing degree of host specific adaptation. For this to be true there must be a fitness deficit for maintaining pathogenic capacity on a wide range of hosts. Investigations of bacterial pathogens provide some evidence for this contention.

*Pseudomonas syringae* and *Xanthomonas campestris* comprise host-specific biotypes (pathovars). A few genes encoding "effector proteins" have been characterized from these bacteria that have pleiotropic effects on virulence and host range.\textsuperscript{[1]} Specific gene-for-gene mediated recognition (discussed later) of the "effector protein" by plants carrying a particular "matching" resistance gene (R gene) results in an incompatible interaction—the host is classed as resistant and the pathogen is classed as avirulent. For this reason, genes encoding "effector proteins" were first recognized by this avirulence trait (and called \textit{avr} genes). However, in addition to being the means by which plants recognize and respond to the presence of the bacterium, "effector proteins" also fulfill a virulence function as demonstrated by comparative studies of the growth in planta of bacterial isolates with or without functional \textit{avr} genes.

**PRESENT-DAY HOST–PATHOGEN INTERACTIONS: SOME EXAMPLES**

A few observations from present-day host–pathogen interactions, placed into a phylogenetic context, serve to illustrate some of the points developed above.

Among the Peronosporales (Oomycetes), there are species of *Pythium* that are considered to be saprotrophs, those that are weak pathogens and those that are destructive, necrotrophic, polyphagous root pathogens. Within the same taxonomic family (Pythiaceae), *Phytophthora cinnamomi* is also a necrotrophic, polyphagous root pathogen (known to attack over 950 plant species) but, while most other species of *Phytophthora* share the necrotrophic mode of nutrition, they exhibit a much more restricted host range. Species in the closely related family Peronosporaceae (the downy mildews) are, by comparison, biotrophic pathogens that exhibit a high degree of host–species specificity with individual pathogen species adapted to distinct host families and subspecific variants being pathogenic on only one or a few closely related plant species within that family.

Within the Ascomycotina, the tribe Helotiales comprises a large number of destructive necrotrophic pathogens but some, such as *Sclerotinia sclerotiorum* and *Botryotinia fuckeliana*, invade a large diversity of host species while others are restricted to particular host families, genera, or individual species. In contrast the tribe Erysiphales (the powdery mildews) comprises a number of exclusively biotrophic genera. While the pathogenesis
of most species and sub-specific variants (formae speciales) is restricted to one or a few closely related species, others, such as Erysiphe orontii, E. cicheracearum and, Oidium lycopersicae have a wide host range.

HOST SPECIFICITY AND CO-EVOLUTION

There is an assumption that to derive nutrition from living plant tissues, a potential pathogen must be able to evade or render ineffective a multiplicity of constitutive physical and chemical defenses in addition to those that are provoked in active response to attempted colonization. The inaccessibility of most plant species to all but a small number of potential pathogenic agents is referred to as ‘‘non-host resistance.’’ Co-evolution can be conceived as a process whereby the components of non-host resistance are sequentially assembled in evolutionary time and give rise to the degree of host specificity observed in present-day host–pathogen associations. The suggestion is that the diversity of these defenses parallels the evolution of plant species and the pathogens to which they are accessible. Such defenses might include: insensitivity to pathogen-derived toxins or hydrolytic enzymes, failure to deliver physical or chemical cues necessary for pathogen development, as well as synthesis of preformed or induced antimicrobial metabolites. In fact, experimental evidence to support these ideas is scarce. In a few specific cases, the importance of plant surface topography as a stimulus for elaboration of infection structures has been clearly demonstrated as has the importance of anti-microbial de-toxification mechanisms for successful pathogenesis.

An alternative hypothesis is that all plant cells have the capacity to recognize non-self and to actively elaborate a defense response. In this hypothesis, it is envisaged that the defense response of all plants is essentially similar except for subtle phylogenetic variations on the theme; host specificity and the process of co-evolution reside in the recognition process. Pathogenesis results when an invader fails to deliver a signal that the plant’s surveillance apparatus can detect or, alternatively, when the cellular machinery required for the surveillance apparatus to function is destroyed (in the case of pathogens that rapidly kill cells without requiring close contact). It is known that micro-evolutionary change over short time periods is mediated by a gene-for-gene relationship involving the recognition of pathogen derived molecules for which within-taxon variation occurs (discussed later). It is envisaged that recognition events mediating non-host resistance could involve taxon-specific molecules that are invariant and biologically essential to the potential pathogen. Consequently, genotype-specific interactions between host plants and their pathogens mediated by gene-for-gene recognition (discussed in the following) may simply represent the “tip of an iceberg” in this type of surveillance and response based defense. The identification of a plant receptor involved in response to a conserved domain of bacterial flagellin provides evidence for this notion.

THE EVOLUTION OF SPECIFIC RECOGNITION: THE GENE-FOR-GENE RELATIONSHIP

The gene-for-gene relationship is a compelling and unifying concept in plant pathogenesis. Table 2 in Crute et al. provides a summary of the basic properties of a gene-for-gene interaction. Over the last century, many hundreds of so-called plant R genes have been identified by their capacity to mediate pathotype-specific resistance to particular pathogens. Over the last ten years, some tens of these R genes have been isolated and sequenced with details of their evolutionary origins and the way they are organized within plant genomes emerging from associated studies. Several different classes of R genes exist in plants and access to whole genome sequences now indicates the existence of about 150 “resistance gene analogs” (RGAs) in one genotype of Arabidopsis thaliana and about 1700 in rice (of which function has only been attributed to relatively few). R genes with structural homology are now known to mediate resistance to parasitic agents as diverse as fungi, oomycetes, bacteria, viruses, nematodes, and aphids.

Although allelic variation at single R gene loci does occur, RGAs are commonly clustered within complex loci comprising a variable number of paralogs that have arisen by gene duplication. Out-crossing and recombination, random mutation, interallelic recombination, gene conversion and unequal crossing-over (resulting in gene duplications and deletions) provide mechanisms for the generation of allelic and haplotypic variation on which selection can act. Time-scales over which variation is generated and selected as well as the processes involved in selection are the subject of debate and investigation.

In addition, selection may favor the observed physical association of genes that are structurally unrelated but contribute to R gene function.

CONCLUSION

The protein products of R genes are believed to function as components of a signal-transduction system. A putative receptor system recognizes molecules indicative
of pathogen presence and activates the plant’s generic defense responses. The receptor and signaling system has numerous components that are being revealed by genetics and cell biology\textsuperscript{11} with previously characterized R genes representing one such component. Recognition specificity may be contributed primarily, but not exclusively, by a LRR common to the proteins encoded by different classes of R gene. This domain comprises a variable number of repeats of the motif xLxLxx putatively providing an array of solvent-exposed ligand-binding surfaces. For several R gene families, regions of the LRR have been shown to be under diversifying selection as indicated by a ratio of greater than one for the synonymous to non-synonymous substitutions of the nucleotides encoding residues.\textsuperscript{2,9,10} On the basis of phenotypic specificity, there is no evidence that any one R allele has affinity for more than one ligand. However, there is no intrinsic reason why this would not be the case and the degree of ligand affinity is likely to be another attribute of RGAs on which selection will act.

Astronomical sequence variation is likely to be manifested by RGAs represented within a single plant genome, within the genepool of a particular plant population and among the diversity of a genotypes represented by any particular plant species. Within and between individual plants the way in which the molecular machinery for signal recognition and transduction is assembled may be subject to combinatorial variation. Such variation may allow individual plants to recognize and respond effectively to molecules that represent the invariant signature of potential pathogens (such as bacterial flagellin) to which the plant is a non-host.\textsuperscript{7} At the same time, the system can provide access to the necessary genetic variation to facilitate a micro-evolutionary response to the tiny sub-set of pathogens of the host species that are detected only by genotypically variant molecular cues on which selection acts to enhance pathogen success. Experimental evidence will probably be forthcoming to establish whether genotype-specific and non-host resistance are indeed mediated through essentially similar signaling pathways differing only in the number of ligands detected or the extent to which the ligand molecule is variant and dispensable or invariant and indispensable to the potential pathogen.

INTRODUCTION

The technology of bioengineering plants to produce recombinant therapeutics has become commonplace. Transgenic plants are emerging as suitable alternatives to transgenic animals and bioreactor-based systems for recombinant protein production (e.g., bacterial, yeast, and insect cells). This trend is yielding a recombinant protein expression system that has increased economic viability and a greater capacity for producing lifesaving protein therapeutics and biopolymers. In addition, plant products are free of mammalian viruses, prions, or other adventitious organisms harmful to humans, making them safer production systems. A wide variety of recombinant protein molecules have been successfully produced in plants (Table 1). This section briefly describes some representative proteins and the role of PTMs on these molecules.

IMMUNOGLOBULINS

IgG and IgA are multifunctional glycoprotein immune molecules that bind to antigens, form immune complexes, and activate classical and alternative complement pathways, respectively. This activity leads to the destruction and clearance of the pathogen. Both IgG and IgA are glycosylated, and although glycosylation is not required for antigen binding, it is critical for activation of the complement pathway. Deglycosylated or underglycosylated immunoglobulins (IgG and IgA) are unable to activate the effector mechanism and therefore fail in the clearance of the pathogen and other antigenic moieties. Plants are able to perform expression and assembly of immunoglobulin (Ig) heavy and light chains into functional antibodies. Plants have been used for production of different forms of antibodies that include full-size IgG and IgA, chimeric IgG and IgA, single-chain Fv fragments (ScFv), Fab, and heavy-chain variable domains; the last three types do not require glycosylation. Among the antibodies that have been successfully produced in plants are those against surface antigen of Streptococcus mutans, the causative agent of dental caries; herpes simplex virus, carcinomaembryonic antigen (CEA), a tumor-associated marker; and single-chain Fv fragments against non-Hodgkins lymphoma. The majority of plant-derived antibodies possessed high-mannose and hybrid-type, α1-3 fucose- and β1-2 xylose-containing structures that lack β1-4 galactose and the terminal sialic acid residues. Expression of mammalian β1-4 Galtransferase in plants resulted in synthesis of galactose-containing antibodies. About 30% of N-glycans of the antibodies were galactosylated. Plant-derived antibodies do not show any alterations in affinity toward antigens or stability in vivo or in vitro.

VACCINES

Plants are a prime candidate for the production of vaccines because of the lower cost of production and the feasibility of producing “edible vaccines.” This technology can be transferred to developing nations relatively easily compared to other expression systems. Some of the representative examples are provided here:

Rabies vaccine: The rabies virus glycoprotein G and nucleoprotein N are both very important in designing an appropriate vaccine. G protein is the major antigen responsible for induction of protective immunity, and N protein is responsible for induction of virus-specific T cells. A plant-derived oral vaccine against a fusion protein consisting of glycoprotein G, nucleoprotein N, and alfalfa mosaic virus coat protein was made, which produced significant immune response and rabies virus–specific antibodies in both mice and humans.

Human cytomegalovirus: Human cytomegalovirus (HCMV) is a member of the herpes virus family that is transmitted by blood and body secretions. In immuno compromised individuals, infection of HCMV can lead to damage of the central nervous system and death. Glycoprotein B, a transmembrane envelope protein, was used to produce oral vaccine against the viral infection. The affinity of recombinant glycoprotein B was examined in
vitro by its ability to bind monoclonal antibodies. Plant-derived glycoprotein B showed a high affinity to antibodies.[9]

**Gastroenteritis coronavirus:** Swine-transmissible gastroenteritis virus (TGEV) is the causative agent of acute diarrhea of newborn piglets. Neutralizing antibodies against this virus are mainly directed toward a surface component, glycoprotein S. Glycoprotein S from TGEV, produced recombinantly in plants, can function as a vaccine against infection when injected intramuscularly in animals. Glycoprotein S has three glycosylation sites, which play an essential role in conformation of this protein. However, no further information on glycosylation of the recombinant glycoprotein S is available.[10]

**Measles virus:** Measles is a highly contagious viral disease. Severe infection may lead to pneumonia, encephalitis, and death. Hemagglutinin, a surface protein from measles virus, was expressed in plants. For recognition of hemagglutinin by B lymphocyte cells, an appropriate conformation of the protein is essential. Folding, stability, and protease susceptibility of this protein is dependent on four N-glycosylation sites. Plant-derived hemagglutinin was found to be stable and able to induce an immune response in animal model systems upon oral administration. This indicates that plants are able to achieve sufficient glycosylation required for stability and folding of the protein.[11]

### OTHER PROTEIN THERAPEUTICS

**Follicle-stimulating hormone:** Follicle-stimulating hormone (FSH) is a pituitary heterodimeric glycoprotein hormone that requires N-glycosylation for subunit folding, assembly, targeting, and stability. FSH produced in plants possesses terminal mannose residues and is reported to be biologically active.[12]

**Lactoferrin:** Lactoferrin is a milk protein. In humans, it is known to contain two N-acetylactosamine-type N-glycans that also contain fucose and sialic acid residues. Lactoferrin belongs to the family of transferrin with iron-binding properties. It has also been found to possess antibacterial, antifungal, antiviral, and antiinflammatory activities. Full-length lactoferrin with antimicrobial properties is produced in plants.[13]

**Erythropoietin:** Erythropoietin (EPO), an N-glycosylated protein that regulates the formation of erythrocytes in mammals, was recombinantly produced in plants. EPO produced in tobacco cells was glycosylated with N-linked oligosaccharides that did not possess terminal sialic acid residues. EPO produced in tobacco exhibited in vitro biological activities by inducing the differentiation and proliferation of erythroid cells. However, it did not show in vivo biological activities.[14] The authors speculated that this was attributable to the different glycosylation of EPO produced in tobacco cells as compared to authentic human EPO and was cleared from circulation by asialo-receptors.

**Macrophage Activating Factor:** Macrophage activating factor (MAF), also known as vitamin D-binding protein and Gc-globulin, is a multifunctional abundant serum protein. Threonine-420 of domain III of MAF is O-glycosylated. Upon infection with pathogen or tumor cells, activated T and B lymphocyte cell surface exoglycosidases remove sialic acid and galactose residues, leaving a GalNAc attached to the threonine.[15] This GalNAc is essential for MAF to bind to the C-type lectin on the cell surface of mononuclear phagocytes, which leads to their activation. Activated phagocytes remove pathogens and tumor cells from the body. Efforts are underway to express this serum glycoprotein in plants.

**Acetylcholinesterase:** Acetylcholinesterase (AChE) catalyzes the degradation of acetylcholine, a neurotransmitter. AChE is a potential therapeutic against organophosphate-based chemicals and warfare agents. Sialic acid residues on the N-glycans of AChE are crucial in determining the circulatory clearance rate. Production of AChE in HEK-293 cells led to hyposialylation of the protein, which was responsible for rapid clearance of recombinant AChE from the circulation. Recombinant human AChE was produced in tomato plants by Mor et al.[16] Kinetic studies of the recombinant AChE using inhibitors showed that the plant-produced AChE had an

inhibition profile similar to the commercially available AChE purified from human erythrocytes. However, in vivo activity, serum half life, and glycosylation studies of plant-produced AChE have not yet been reported.

BIOMOLECULES

Collagen: Collagen is the major protein in the extracellular matrix and thus the most prominent animal protein. There are more than 20 different types of collagens described so far. The triple-helical domains of collagens have the repeating amino acid sequence (Gly- X-Y)n, where X and Y are frequently proline and hydroxyproline, respectively. Collagen molecules go through multiple PTMs involving at least eight enzymes and cofactors. Specific proline and lysine residues are hydroxylated, and some of the hydroxylysine residues are further modified by glycosylation with galactose-glucose disaccharide units. Hydroxylation of proline to hydroxyproline residues assists in trimer assembly of collagen polypeptide chains. Collagens and their derivative molecules (gelatin) have multiple applications but are currently only available from animal sources. There is a need for alternative sources to produce large quantities of pure and safe collagens. Human collagen β-1 (C1z1) has been expressed by itself and with the multisubunit recombinant prolyl-4-hydroxylase[17] in transgenic tobacco, collagen trimers have been produced that are stable up to 37°C. These reports suggest that the production of human collagen is possible in plants. However, further research is required to understand and improve recombinant collagen synthesis and assembly in plants.

CONCLUSION

The discovery of and demand for medically important proteins are growing rapidly. It is becoming increasingly critical to ensure their availability in sufficient quantity for research, therapeutics, and diagnostic uses. Transgenic plants are emerging as suitable systems for the production of functional recombinant human proteins. Plants have the distinct advantages over other expression systems of product safety, economical production, and ease of scale-up. Plants are also able to perform most PTMs that are carried out by mammals, such as glycosylation, phosphorylation, and hydroxylation. However, the PTMs in plants are under-studied and require more attention because it is important to control the addition of and evaluate the structural and functional roles of these modifications on recombinant products for regulatory purposes as well as for desired physiological activities, when used for therapeutic purposes in humans and animals.

INTRODUCTION

Plant growth and yield potential are significantly influenced by various abiotic stresses such as drought, salinity, and cold. A common feature found in plants grown under water stress is a transient increase in the level of the phytohormone abscisic acid (ABA), which returns to control level promptly following relief of the stress. ABA plays important roles in many aspects of plant growth and development such as embryo maturation, seed dormancy, germination, stomatal aperture, as well as sugar signaling and regulation of expression of stress-responsive genes. Utilizing genetic and biochemical approaches, the ABA biosynthetic and catabolic routes have been recently outlined in higher plants. An important challenge in the future is to understand how plant cells sense and transduce the water stress signal to induce ABA biosynthesis and inhibit ABA degradation.

ABA ACCUMULATION IN PLANTS UNDER WATER STRESS

The natural 5-(+)-ABA is ubiquitous in all photosynthetic organisms but not in bacteria.[7] In mesophytic plants, the endogenous levels of ABA can rise 10-fold to 50-fold in water-stressed leaves, and return to prestress levels once the plants are rewatered, usually within 4–8 hr.[8] The primary cue for initiating ABA accumulation in water-stressed tissues is not clear, although an acute rise in ABA content correlates well with leaf water potential falling below −1.0 MPa and decreased stomatal conductance. The increased ABA levels are probably caused by greater rates of synthesis and increased import from surrounding tissues, whereas the decreased concentration is because of reduced synthesis, robust catabolism, inactivation by conjugation of ABA to its glucose ester (GE), and possible effluxes.[5,7] The increased rate of de novo ABA synthesis in water-stressed tissues requires gene transcription and protein synthesis because it can be blocked by inhibitors of transcription such as actinomycin D and cordycepin, and by inhibitors of protein synthesis such as cycloheximide.

BIOSYNTHESIS OF ENDOGENOUS ABA

Through the cloning of genes from mutants impaired in ABA biosynthesis, combined with the use of inhibitors of ABA biosynthesis and in vivo $^{18}$O$_2$ labeling studies, it is clear that ABA is derived from an oxygenated carotenoid precursor ($C_{40}$). The studies also suggest that the early steps of ABA biosynthesis are localized to the plastids.[6,7]

Based on our current understanding,[1,2,6,7] the major ABA biosynthesis route has emerged (Fig. 1). In the plastids, the carotenoids are synthesized from the $C_5$ precursor, isopentenyl pyrophosphate (IPP). Plastidic IPP is synthesized from glyceraldehyde-3-phosphate and pyruvate via 1-deoxy-D-xylulose-5-phosphate (DXP). Subsequently, IPP is converted to a xanthophyll zeaxanthin via several intermediate products including a $C_{20}$ geranylgeranyl pyrophosphate (GGPP), a $C_{40}$ phytoene, and $\beta$-carotene.

The epoxidation of zeaxanthin and antheraxanthin to all-trans-violaxanthin is catalyzed by zeaxanthin epoxidase (ZEP; encoded by ABA1/AtZEP1 in Arabidopsis and ABA2 in tobacco). Subsequently, during the first committed step in ABA biosynthesis, 9-cis-violaxanthin and 9'-cis-neoxanthin ($C_{40}$) are further oxidatively cleaved by 9-cis-epoxycarotenoid dioxygenase (NCED; encoded by AtNCED in Arabidopsis and VP14 in maize) to generate xanthoxin ($C_{15}$) and a $C_{25}$ apocarotenoid by-product. Following entry into the cytosol, xanthoxin is converted first to ABA aldehyde by xanthoxin oxidase/short-chain alcohol dehydrogenase (encoded by Arabidopsis ABA2/GIN1), and then to ABA by ABA aldehyde oxidase (AAO). The function of AAO requires an activated form of a molybdenum cofactor, which is generated by a sulfurase enzyme (encoded by ABA3/LOS5). It should be pointed out that there appears to be an alternative route converting abscisic alcohol to ABA.[5–7] The NCED-catalyzed oxidative cleavage of 9-cis-violaxanthin and 9'-cis-neoxanthin is considered as the critical rate-limiting step in the ABA biosynthesis pathway in higher plants.[1,9]
CATABOLISM OF ABA

The amount of ABA present in a tissue is regulated dynamically through not only biosynthetic inputs as described above, but also through catabolic outputs, as summarized below. Of several metabolic pathways by which endogenous ABA can be degraded or inactivated, the predominant catabolic pathway is through the 8'-hydroxylase-catalyzed formation of 8'-hydroxy ABA, which is unstable and can cyclize to result in (−)-PA. PA can be further reduced to dihydrophasic acid (DPA). Other minor alternative catabolic pathways may also exist because trace amounts of other metabolites, including (+)-7'-hydroxy ABA, are found in certain plants. ABA can also be inactivated through the formation of ABA conjugates such as ABA GE.

REGULATION OF ABA BIOSYNTHESIS AND CATABOLISM GENES BY WATER STRESS

The expression levels of several ABA synthesis genes including ZEP (LOS6/ABA1, zeaxanthin epoxidase), NCED3, AAO3, and MCSU (LOS5/ABA3 and molybdenum cofactor sulfurase) are upregulated by drought and salt stress, but not obviously induced by cold. Some of the ABA biosynthesis genes are also upregulated by ABA itself, suggesting that there is a positive feedback loop in regulating ABA biosynthesis (Fig. 1). In Arabidopsis, ZEP is expressed in most tissues and upregulated by water stress in roots and shoots of wild-type plants, but not in ABA-deficient or ABA-insensitive mutants. Furthermore, the expression of both ZEP and NCED3 fluctuates in leaves in a diurnal pattern.

Fig. 1 Water stress induces ABA accumulation (closed boxes) by inducing biosynthesis genes. Also shown is the positive feedback regulation (thick arrows) of the biosynthesis genes by ABA. The ABA signaling components (dashed box) may also impact ABA biosynthesis through feedback regulation. (View this art in color at www.dekker.com.)
NCED3, expressed in all tissues examined, is the only member of the nine-gene family in Arabidopsis that is highly induced by NaCl and dehydration, but its induced expression by exogenous ABA varies among ecotypes. Expression studies in other species indicate that water stress-induced ABA levels correlate well with both transcript and protein accumulation of NCED. The fact that NCED is not substantially upregulated by ABA supports the notion that it is the initial rate-limiting step in ABA biosynthesis.\(^8\) ABA2 is expressed constitutively and not significantly upregulated by exogenous ABA or water stress. AAO3 is induced by water stress in leaves but not in roots.\(^6\) The catabolic enzyme, \(8\)'-hydroxylase, is also induced by exogenous ABA, although the identity of the gene encoding this enzyme has not been reported. Water stress appears to induce the expression of the ABA biosynthetic genes, possibly through a \(Ca^{2+}\)-mediated protein phosphorylation cascade (Fig. 1). The signaling pathways downstream of ABA also modulate ABA biosynthesis by affecting the positive feedback regulation of the biosynthesis genes. Through an unknown mechanism, ABA sensitivity is controlled by RNA metabolism, which in turn is regulated by ABH1 and SAD1.\(^4\) The sad1 mutation impairs the ABA upregulation of AAO3 and MCSU genes and results in ABA deficiency and a drought-hypersensitive phenotype, indicating that the feedback loop of ABA biosynthesis is indirectly regulated by SAD1. The feedback loop is also partially impaired in the ABA-insensitive mutant abi1, but not in abi2.\(^8\)

**CONCLUSION**

Although substantial advances are being made in our understanding of the ABA biosynthesis genes, little is known about their regulation by water stress. The crosstalk between ABA signaling cascades and ABA biosynthetic and catabolic pathways is not clearly understood. The identification of osmotic stress sensor(s) and ABA receptor(s) and their downstream signaling components awaits further genetic, molecular, biochemical, and cell biological studies. Understanding these pathways will facilitate efforts to manipulate the endogenous ABA content to improve water stress tolerance in plants.

Plant Response to Stress: Abscisic Acid Fluxes

Wolfram Hartung
Universität Würzburg, Würzburg, Germany

INTRODUCTION

Water relations and stress tolerance of plant cells and tissues of crop plants are significantly improved when abscisic acid (ABA) concentrations are high. This occurs by closing the stomata, stimulation of water uptake into roots, and induction of developmental changes that improve the stress tolerance in plants. Such plants perform particularly well under arid conditions. Stress-tolerant crop varieties often exhibit high ABA concentrations and treatments that intensify long distance ABA signaling reduce water consumption and, in the case of grapevine, improve the quality of the berries. The knowledge of mechanisms that increase ABA concentration in organs under mild and severe stress are also of special interest for agricultural and horticultural scientists.

ABA accumulation in cells, tissues, and organs may be a result of an altered ABA metabolism (increased biosynthesis and/or decreased degradation). The rates of these biochemical processes, however, are rather slow. ABA fluxes that may be influenced under stress can be a much more effective, sensitive, and rapid mechanism to maintain ABA homeostasis and to change rapidly ABA concentrations in cellular compartments, cells tissues, and organs. In this article, ABA fluxes will be discussed at the membrane, tissue, and organ level. Mild (hypoosmotic) stress conditions that are not sufficiently severe to stimulate ABA biosynthesis in leaves and root tips are discussed predominantly.

ABA FLUXES ACROSS BIOMEMBRANES

Roots

ABA fluxes across membranes have been investigated in detail using the efflux compartmental analysis. When barley roots were stressed hypoosmotically with sorbitol ABA, fluxes across the plasmalemma of both cortical and xylem parenchyma cells where reduced, and the flux across the tonoplast was stimulated, resulting in an increased cytosolic ABA concentration in the root cells.[1,2]

ABA fluxes into the surrounding rhizosphere can be particularly severe when the soil solution is alkaline. Under such conditions, ABA leaks from roots into the soil solution, especially when they lack Casparian bands in their hypodermis. An undesirable efflux can be avoided when the ABA concentration in the soil solution of the rhizosphere is sufficiently high. Thus, an equilibrium between internal and external ABA is maintained.[3]

Mesophyll Cells, Epidermal Cells, and Guard Cells

ABA fluxes across plasma membranes and tonoplasts of mesophyll and guard cells have also been investigated using the efflux compartmental analysis. Again, sorbitol was used as an osmoticum to establish hypoosmotic and hyperosmotic stress. ABA flow across the plasma membranes of the guard cells of Valerianella locusta is reduced significantly under hypoosmotic stress, whereas the ABA flux across the tonoplast is only slightly affected. This results in a transiently increased apoplastic and a reduced cytosolic ABA concentration. It was concluded[2] that the ABA increase in the apoplast is of special physiological importance in terms of stress, because those structures that may recognise ABA at the guard cells seem to be located on the outer surface of the guard cell plasma membrane.[3] The ABA fluxes across the plasma membrane of barley epidermis cells have also been investigated. They are facilitated by a carrier that becomes active when the apoplastic pH of stressed leaves is increased and excess ABA has to be removed from the leaf apoplast to the surrounding tissues.[4]

It should be pointed out that efflux experiments described here have been performed under equilibrium conditions. In an intact plant, however, delivery of ABA from other organs and changes of ABA metabolism must also be considered. All of these additional processes that have an impact on ABA gradients across membranes have been incorporated into a mathematical model that quantitatively describes ABA flows under the complex fluctuating conditions that occur in the natural habitat.[3]

Stem and Mesocotyl Parenchyma

During its long distance transport in the xylem of bean internodes and maize mesocotyls, ABA can be redistributed to the surrounding tissues. If ABAxyl is low, those
tissues can release ABA into the xylem with rates of approximately 1 pmol m\(^{-2}\) s\(^{-1}\).[5,6] These tissues play an important role for the ABA homeostasis in the xylem vessels of stems.

**ABA FLUXES BETWEEN TISSUES**

The ABA flows between root cortex and root stele are of particular physiological interest with regard to stress. Large quantities of root ABA have to be transported laterally from the cortex across the endodermis into the xylem parenchyma and into the xylem vessels. In the case of a symplastic transport, ABA has to pass the plasmalemma of xylem parenchyma cells to reach the xylem vessels. This is a rate limiting step that is much slower than water transport into the xylem. When the water flow is increased by transpiration, ABA\(_{xyl}\) is diluted. An apoplastic transport of ABA by solvent drag across the endodermis would compensate or even overcompensate this dilution, provided their Casparian bands are permeable for ABA. Indeed, a significant apoplastic bypass flow of ABA could be detected in maize roots. The intensity of the apoplastic bypass flow of ABA depends on the species, the pH of the root cortical apoplast and the apoplastic ABA concentration.

The other important apoplastic barrier of the roots, the exodermis, prevents ABA loss into the soil solution, especially under nontranspiring conditions. This explains the tolerance of plants with exodermises to alkaline soils of arid habitats compared to those without an exodermis, mainly the Fabaceae, which are unprotected.[5–8]

**LONG DISTANCE ABA FLOWS BETWEEN ORGANS**

Root-to-shoot flows of ABA are of special interest under conditions of mild stress when water relations of the leaves are not affected. The roots, however, experience stress as the soil is drying. ABA flows between organs have been investigated predominantly with *Ricinus communis* and *Lupinus albus*, which allow harvest of both transport fluids, phloem and xylem sap. Long-distance signaling has been reviewed recently in detail.[5,6,9]

The ABA flow from the root to the shoot in the xylem is increased by moderate salt stress in lupins tenfold, and in castor bean fivefold. This ABA did not originate exclusively from biosynthesis in the roots. A significant portion is recirculated in the phloem from the leaves via roots back to the shoot. This portion of recirculated ABA was increased under salt stress in *Lupinus* and in *Ricinus* two to three fold. The ABA signal in the xylem of *Ricinus* is also increased threefold when nitrate in the nutrient medium is replaced by ammonium. Under phosphate deficiency that often occurs in alkaline soils of extreme arid habitats, the root-to-shoot flow of ABA is increased tenfold, whereas nitrate deficiency has only a weak negligible effect. Potassium deficiency causes a fourfold higher root-to-shoot ABA flow in the xylem.[10]

When nitrate or ammonium is sprayed to the leaves of *Ricinus* and the root medium is kept N-free, ABA biosynthesis of nitrate-sprayed plants is increased, resulting in stimulated ABA transport in the phloem to the roots where most of the ABA is metabolised. In ammonium-sprayed plants, a significant amount of ABA biosynthesis can be observed in the roots, resulting in an increased root-to-shoot flow compared to nitrate-sprayed plants. This resembles strongly the situation of plants where roots were supplied with ammonium. A shoot-to-root signal of ammonium-sprayed plants that causes ABA biosynthesis in the roots and ABA transport in the xylem must be postulated. This signal is unknown.[9]

**ABA Flows from the Shoot to the Root**

A role of ABA as a shoot-to-root signal has been postulated for *Ricinus* seedlings that increases the ABA flow in the phloem under mild water deficiency by fiftyfold. Intact lupins and castor beans showed a two- to fivefold increase of phloem ABA flow under conditions of salt and ammonium stress but not under conditions of phosphate and nitrate deficiency. Maize plants that were cultivated with only their seminal roots experience water stress in the leaves because water flow was restricted by the constant number of xylem vessels. As a result, not only was ABA increased in the leaves (tenfold), but also surprisingly in the roots. This is most likely due to increased phloem transport because an increase of ABA synthesis in the unstressed, well-hydrated and nutrient-supplied roots seems to be extremely unlikely. The ABA delivered by phloem transport to the roots may stimulate the development and the hydraulic conductivity of the root systems under stress.[7,9]

**LONG DISTANCE FLOW OF ABA CONJUGATES**

It has been postulated repeatedly that ABA conjugates, predominantly the ABA-glucose ester (ABA-GE), act as hormonal root-to-shoot stress signals. Indeed, an increased xylem transport of ABA-GE has been observed in the xylem sap of drought- and salt-stressed barley, maize, rice, and sunflower plants. Since ABA-GE is extremely hydrophilic, it is transported in the xylem over long distances without any loss by redistribution to the surrounding stem parenchyma. On the other hand, it cannot pass apoplastic barriers in roots and be taken up into mesophyll cells after its arrival if the leaf apoplast is
extremely small. Specific esterases in the root and leaf apoplast release free ABA from its conjugate. Afterward, ABA can be redistributed to the surrounding cells. In leaves the activity of these esterases is increased significantly under salt stress which provides a further mechanism to increase the ABA at the site of action in stressed leaves.\[7,9,11\]

**CONCLUSION**

Environmental stresses influence flows of the stress hormone ABA on cellular, tissue, and organ levels, which results in altered concentrations of this universal plant stress hormone at the primary site of the target cells and tissues. Flows are altered already under mild stress conditions. Thus, ABA can be increased without affecting the biosynthesis and metabolism of ABA. The root-to-shoot ABA signal can be intensified by special cultivation techniques, such as partial root drying (PRD). In both the greenhouse (tomato\[12\]) and under field conditions (grapevine\[13\]), when water was withheld from only a part of the root system while the other was irrigated, ABA concentration in the xylem was increased markedly. Changes of fertilization (ammonium versus nitrate) may also enhance long-distance flows from the roots to the shoots \[9,10\] The resulting ABA increase in the leaves and the fruit reduces the water consumption without significant negative effects on the yield. Additionally, PRD has a positive effect on those factors that control the fruit quality of tomato and grapevine (sugars, acids, pigments, etc.). The knowledge of the mechanisms that modify ABA fluxes in crop and fruit plants is of practical and commercial interest, especially for agriculture in arid climates.

Plant Response to Stress: Biochemical Adaptations to Phosphate Deficiency

William C. Plaxton
Queen’s University, Kingston, Ontario, Canada

INTRODUCTION

Phosphate (Pi) is an essential macronutrient that plays a central role in virtually all metabolic processes in plants, including photosynthesis and respiration. Despite its importance, Pi is one of the least available nutrients in many ecosystems, and is a frequent limiting factor for plant productivity. Although plentiful in the earth’s crust, soil Pi often exists in insoluble mineral forms that render it unavailable to plants. Agricultural Pi deficiency is alleviated by the massive application of Pi fertilizers, currently estimated to be about 40 million metric tons per year worldwide. However, the assimilation of Pi fertilizers by crops is quite inefficient, as a large proportion of applied Pi becomes immobile, or may runoff into and thereby pollute nearby surface waters. Moreover, the world’s reserves of rock Pi (mined for production of Pi fertilizers) are expected to be depleted within the next century. Thus, studies of the complex mechanisms whereby plants acclimate to nutritional Pi deficiency are of great importance. This could lead to the development of rational strategies for engineering Pi-efficient transgenic crops that would reduce or eliminate our current overreliance on expensive, polluting, and nonrenewable Pi fertilizers. The aim of this article is to provide a brief overview of the fascinating biochemical adaptations of Pi-starved (−Pi) plants.

THE PLANT PHOSPHATE-STARVATION RESPONSE

Plants have evolved the ability to acclimate, within species-dependent limits, to extended periods of Pi deficiency. Pi deprivation elicits a complex array of morphological, physiological, and biochemical adaptations, collectively known as the Pi-starvation response. Plant morphological/physiological adaptations that enhance the acquisition of limiting Pi from the soil include increased root growth relative to shoot growth, as well as root coloniziation by mycorrhizal fungi.1,2

Mycotrophic Versus Nonmycotrophic Plants

Symbiotic mycorrhizal fungi help mycotrophic plants increase Pi-uptake from Pi deficient soils. In return, the host plant supplies sucrose to fuel the energy demands of the mycorrhizal symbiont. Mycorrhizae colonize the roots of most plants, except for the nonmycotrophic minority that include members of the Cruciferae, Chenopodiaceae, and Proteaceae families. It is notable that many nonmycotrophs, such as buckwheat and white lupin, are notorious for their ability to thrive on infertile soils. This reflects the view that relative to mycotrophic plants, the nonmycotrophs appear to have evolved to allow more efficient acclimation to low Pi conditions.2

BIOCHEMICAL ADAPTATIONS OF PHOSPHATE-STARVED PLANTS

Adaptation #1: Increased Efficiency of Cellular Phosphate Uptake

Multiple plasmalemma Pi transporters are differentially expressed under varying Pi nutritional regimes.1,2 The widely accepted dual Pi uptake model is characterized by constitutive low-affinity and Pi-starvation inducible (PSI) high-affinity Pi transporters that respectively function at high (mM) and low (μM) concentrations of external Pi. High-affinity Pi transporters likely play a crucial role in the acquisition of limiting external Pi by −Pi plants.1,2 Genome sequencing has indicated that Arabidopsis contains nine members of the high-affinity Pi transporter gene family, but only a single low-affinity Pi transporter gene.

Adaptation #2: Induction of Phosphate Scavenging and Recycling Enzymes

2A: Acid phosphatase

Acid phosphatase (APase) induction is a universal symptom of plant Pi stress.2,3 APases function as intracellular
(vacuolar) or extracellular (secreted) Pi salvage systems
that catalyze the hydrolysis of Pi from phosphate-mono-
esters (Fig. 1(a)). The existence of 22 Arabidopsis genes
that putatively encode different APases indicates that plant
APase biochemistry is relatively complex.

2B: Secreted nuclease and phosphodiesterase

Nucleic acids present in decaying organic matter repre-
sent an important source of extracellular Pi that may be
exploited by –Pi plants. Degradation of extracellular
DNA and RNA by PSI-secreted nucleases, phosphodies-
terase, and APase liberates Pi from nucleic acids for its
subsequent uptake by PSI high-affinity Pi transporters of
–Pi plant roots (Fig. 1(b)). [2,4]

2C: Replacement of membrane
phospholipids with nonphosphorus
galacto- and sulfonyl-lipids

–Pi plants can scavenge and conserve Pi by replacing
their membrane phospholipids with amphipathic galacto-
and sulfonyl lipids. Arabidopsis mutants defective in sul-
fonlipid synthase (the terminal enzyme of sulfonyl lipid synthesis)
were recently reported to show impaired growth
during Pi deprivation.[5]

2D: Induction of metabolic phosphate
recycling enzymes

Several PSI glycolytic bypass enzymes such as PPI-
dependent phosphofructokinase (PPI-PFK), phosphoenol-
pyruvate (PEP) phosphatase, and PEP carboxylase (PEP-
Case) may facilitate intracellular Pi recycling, because
Pi is a by-product of the reactions catalyzed by each of
these enzymes (Fig. 2). Their reactions may also facilita-
tate respiration and/or organic acid excretion, while gener-
ating free Pi for its reassimilation into the metabolism of
the –Pi cells.[2]

2E: Organic acid excretion

Scavenging of Pi from extracellular sources may be aided
by the enhanced excretion of organic acids due to
PEPCase induction. Roots and suspension cell cultures
of –Pi plants have been demonstrated to markedly up-
regulate PEPCase.[1,2,6–8] PEPCase induction during Pi
stress has been correlated with the excretion of signifi-
cant levels of organic acids such as malate and citrate.
This leads to acidification of the rhizosphere, which
thereby contributes to the solubilization and assimilation
of mineral Pi from the environment.[1,2,7]

Adaptation #3: Induction of Alternative
Pathways of Cytosolic Glycolysis

As a consequence of the large decline (up to 50-fold) in
cytoplasmic Pi levels that follows severe Pi stress, large
reductions in intracellular levels of ATP and related
nucleoside phosphates can also occur (Table 1).[2,7,8] This
may hinder carbon flux through the enzymes of classical
glycolysis that are dependent upon adenylates or Pi as
cosubstrates (Fig. 2). Despite depleted intracellular Pi

![Fig. 1](image.png)
Fig. 2 A model suggesting various adaptive metabolic processes (indicated by bold arrows) that may promote the survival of –Pi plants. Alternative pathways of cytosolic glycolysis and mitochondrial electron transport, and tonoplast H⁺-pumping facilitate respiration and vacuolar pH maintenance by –Pi plant cells because they negate the dependence on adenylates and Pi, the levels of which become markedly depressed during severe Pi starvation. Organic acids produced by PEPCase may also be excreted by roots to increase the availability of mineral-bound Pi (by solubilizing Ca-, Fe- and Al-phosphates). A key component of this model is the critical secondary role played by metabolic Pi recycling systems during Pi deprivation. Enzymes that catalyze the numbered reactions are as follows: 1) hexokinase; 2) fructokinase; 3) nucleoside diphosphate kinase; 4) UDP-glucose pyrophosphorylase; 5) phosphoglucone isomerase; 6) phosphoglucone mutase; 7) NAD-dependent G3P dehydrogenase (phosphorylating); and 8) 3-phosphoglycerate kinase. Abbreviations are as in the text and as follows: DHAP, dihydroxyacetone-phosphate; Fru, fructose; Glu, glucose; MDH, malate dehydrogenase; OAA, oxaloacetate; 3-PGA, 3-P-glycerate; PK, pyruvate kinase; UQ, ubiquinone.
and adenylate pools, –Pi plants must continue to generate energy and carbon skeletons for key metabolic processes. As indicated in Fig. 2, at least six Pi- and adenylate-independent glycolytic bypass enzymes (sucrose synthase (SuSy), UDP-glucose pyrophosphorylase, Ppi-PFK, nonphosphorylating NADP-glyceraldehyde-3-phosphate (G3P) dehydrogenase, PEPCase, and PEP phosphatase) have been reported to be plant PSI enzymes.[2,6–8] These enzymes are hypothesized to represent PSI bypasses to the adenylate or Pi-dependent glycolytic enzymes (i.e., invertase/hexokinase, ATP-PFK, phosphorylating NAD-G3P dehydrogenase, and pyruvate kinase), thereby facilitating glycolysis during severe Pi stress. Furthermore, as Pi exerts reciprocal allosteric effects on the activity of ATP-PFK (potent activator) and PPi-PFK (potent inhibitor) (Fig. 2),[7] the large reduction in cytoplasmic Pi in –Pi plants should promote the in vivo activity of PPi-PFK while curtailing that of ATP-PFK.[2,8]

**Adaptation #4: Induction of Tonoplast H⁺-Pumping Pyrophosphatase**

In addition to the SuSy pathway of sucrose conversion to hexose-monophosphates, and Ppi-PFK, PPi could be employed as an alternative energy donor for the active transport of protons from the cytosol into the vacuole (Fig. 2). That PPi-powered processes may be a crucial facet of the metabolic adaptations of plants to environmental extremes causing depressed ATP (but not PPi) pools is further indicated by the significant induction of the tonoplast H⁺-PPiase by anoxia, or by severe Pi starvation.[17,9] As indicated in Fig. 2, the induction of PPi-dependent cytosolic bypasses (i.e., tonoplast H⁺-PPiase, Ppi-PFK, and SuSy) may serve – Pi plants by: 1) circumventing ATP-limited reactions; 2) conserving limited cellular pools of ATP; while 3) recycling valuable Pi from PPi.

**Adaptation #5: Induction of Alternative Pathways of Respiratory Electron Transport**

Respiratory O₂ consumption by plant mitochondria can be mediated by the phosphorylating cytochrome pathway or by nonphosphorylating alternative pathways (Fig. 2). The significant reductions in cellular Pi and ADP pools that follow extended Pi deprivation will impede respiratory electron flow through the cytochrome pathway at the sites of coupled ATP synthesis. However, the presence of nonphosphorylating pathways of electron transport provides a mechanism whereby respiratory flux can be maintained under conditions when the availability of ADP and/or Pi are restrictive. Plants acclimate to Pi stress by increased engagement of the nonphosphorylating (i.e., rotenone- and cyanide-insensitive) alternative pathways of respiratory electron transport[2,10,11] (Fig. 2). Moreover, increased levels of alternative oxidase protein may occur in – Pi plants.[10,11] This allows continued functioning of
the citric acid cycle and respiratory electron transport chain with limited ATP production. By preventing severe respiratory restriction, the alternative oxidase has been hypothesized to prevent undesirable redirections in carbon metabolism as well as the excessive generation of harmful reactive O₂ species in the mitochondrial of −Pi plants.⁹,¹⁰ This has been corroborated by the impaired growth and metabolism of −Pi transgenic tobacco plants that are unable to synthesize a functional alternative oxidase protein.¹⁰

### CONCLUSION

Studies of plant responses to nutritional Pi deprivation have revealed some remarkably adaptive mechanisms that contribute to the survival of −Pi plants. Although these adaptations are not identical in all plants, certain aspects are conserved in a wide variety of plants from very different environments. The biochemical adaptations of −Pi plants provides an excellent example of how the unique flexibility of plant metabolism and energy transduction helps them cope in a typically stressful environment. These adaptations also provide a useful system for studies of plant signal transduction and gene expression. Future investigations of these pathways should provide further links between the biochemical and molecular control of plant metabolism. A better understanding of the extent to which changes in flux through alternative enzymes and pathways influences plant stress tolerance is of significant practical interest. This knowledge is relevant to the ongoing efforts of agricultural biotechnologists to engineer transgenic crops that have improved resistance to environmental extremes, including Pi starvation.

### ACKNOWLEDGMENTS

I am indebted to past and present members of my laboratory who have examined the biochemical adaptations of vascular plants, green algae, and yeast to Pi scarcity. Plant Response to Stress: Critical Periods in Plant Development

G. Nissim Amzallag
Judean Regional Center for Biological Research, Carmel, Israel

INTRODUCTION

Development is not a continuous phenomenon. Discrete phases, also termed phenophases, are each characterized by a specific pattern of organogenesis or by specific sensitivity to environmental factors. Replacement of a phenophase by another one generates an intermediate stage of transition that may be termed a critical period. “Between successive critical levels [periods] the system retains its qualitative properties; it must be characterized here by a low sensibility to external and internal changes in developmental conditions (high resistance).” From this observation, Zhirmunsky and Kuzmin concluded that critical periods, characterized by a strong increase in sensitivity to external factors, must be the privileged time for the emergence of new structures and physiological characteristics.

Critical periods have not been given attention in physiology, partly because they are so evanescent, and partly because they are interpreted as a passive transition in the expression of two successive developmental programs. However, their investigation reveals a quite different reality: Critical periods appear to be crucial for maturation of an emerging phenophase and for its adaptive adjustment to environmental constraints.

PHYSIOLOGICAL ADAPTATION TO STRESS

In many plant species, an increase in tolerance to a stress may be achieved following preexposure to a moderate stress.[1] In *Sorghum bicolor*, for example, a three-week pretreatment with 150 mM NaCl (a sublethal concentration) induces an ability to tolerate a concentration of 300 mM NaCl, which is lethal for non-pretreated plants. Further investigations[1] reveal that increased tolerance is induced by pretreatments starting during a short period of competence, termed a developmental window. During this short period, growth and development are strongly affected in plants exposed to stress, and a large increase in diversity emerges within an initially homogeneous population.[1] These observations suggest that the developmental window is not a simple phase of competence for expression of genes for salt resistance. Self-organizing processes seem inherent to maturation of the adaptive response. In *Sorghum*, the developmental window corresponds to the transition from juvenile to mature vegetative development. Other developmental windows have been identified during transition periods,[1] linking them to critical periods in development.[2,3]

WHAT IS A DEVELOPMENTAL WINDOW?

A direct link is not always observed between whole plant and cellular levels of tolerance to moderate salinity.[4] Similar findings are reported concerning heavy metal toxicity or cold tolerance.[1] In all these cases, the whole plant level of organization remains the determining factor for tolerance to moderate levels of stress. This suggests that the main perturbation following exposure to a sublethal level of stress concerns integrative physiology: between-organs relationships and their controlling factors, the plant growth regulators (PGRs). This is why alleviating effects to moderate levels of stress have been frequently observed following exogenous supply of PGRs.[5] Moreover, physiological adaptation may result from a simple change in hormone metabolism or in cellular sensitivity to the hormone.

Indeed, changes in hormone sensitivity are observed in plant tissues. Some authors consider these changes to be the main mode of hormone action, in contrast with the well accepted dose-response mode.[6] These two antagonistic approaches may be integrated in the same framework when considering that dose-response characterizes phenophases and that changes in cellular sensitivity to PGRs are specific to a developmental window. This assumption has been confirmed by observation of changes in hormone sensitivity during this period and by following emergence of new physiological functions on the basis of these changes.[7,8]

Plants cannot move toward a more appropriate environment. In an ecological perspective, the existence of a developmental window after germination may be justified as a process of adjustment of the seedling to a necessarily unpredictable environment. However, this developmental
window has also been identified as a period of hormone resetting for plants growing in optimal environments.\textsuperscript{7,8} In \textit{Sorghum bicolor}, the developmental window identified during early vegetative development corresponds to the transition from seminal to adventitious root systems. As a new organ, the adventitious root system is integrated in the regulation network during aperture of the developmental window already identified for salt-adaptation. For this reason, the developmental window is identified as a critical period of transition between two phenophases. In this context, physiological adaptation to a moderate environmental stress becomes a companion phenomenon of adaptive adjustments to integration of the adventitious roots during normal development. Moreover, the new emerging phenophase is not the simple expression of a preexisting program of development. It is partly elaborated as a function of the initial phenophase and the internal factors disturbed by their emergence. This requirement of an adaptive dimension of development has been suggested from theoretical considerations ("... adaptive changes in the system’s structure and the character of its regulations will be required to balance the new developmental conditions.")\textsuperscript{[9]}

**CHARACTERIZATION OF A CRITICAL PERIOD**

Intuitively, a critical period includes two steps. The first corresponds to dismantlement of the initial hormone regulation network, leading to a transient increase in autonomy of the different parts of the network. The second corresponds to emergence of a new network of regulation through integration of disturbing factors, endogenous as well as exogenous. This dynamic may be followed through measurement of changes in strength of the regulation network. An index, termed connectance, has been defined as the mean strength of linkage between organs generating together the organism. Connectance is measured on a population that is homogeneous as possible exposed to an environment that is as uniform as possible. In such conditions, the $r$ coefficient for linear regression provides information about the degree of linkage in the regulation network. This linkage may be direct or indirect, so that connectance cannot be correctly estimated by analysis of a single couple of parameters. However, when considered together, the $r$ values calculated for all the possible couples inform about the strength of the network.

The $r$ coefficients are not normally distributed, so that connectance cannot be correctly evaluated by averaging their absolute values before transforming them into $z$ values (normally distributed), according to the formula $z = 0.5 \ln[(1 + r)/(1 - r)]$. Connectance is defined as the mean value of all these calculated $z$ coefficients.

Time variations in connectance may be followed after harvesting populations every 2–3 days. By this method, a drop in connectance is especially observed during the beginning of a critical period, and is followed by a gradual increase in emergence of a new phenophase.\textsuperscript{[10,11]} This result does not only confirm initial assumptions, but also provides a tool for investigating factors influencing the expression of a critical period, its intensity (amplitude of drop in connectance), and its duration (time required for stability of the new regulation network). This approach reveals that expression of a critical period varies according to environmental conditions and the genotype considered. Consequently, beyond developmental contingencies related to internal disturbing events, expression of a critical period appears as regulated.

Evidence indicates that brassinosteroids (BRs) are involved in expression of a critical period through their effect on cellular sensitivity to other growth factors. This is why BRs differ so much from other PGRs. They interact with almost all the PGRs already identified, and are involved in stress alleviation.\textsuperscript{[12]} In consequence, BRs should be considered as metahormones of plant development.

**CONCLUSION**

Development is generally understood to be the expression of a genetic program, so that an adaptive dimension is not required. In such a context, when developmental modifications and an explosion of diversity are transiently observed in an initially homogeneous population, they are automatically related to a genetic or environmental (hypothetic) heterogeneity. In this context, it is not surprising that so few studies about critical periods have been published.

Two redundant levels of regulation (local and global) of development coexist in plants, so that a transient decrease at the global level does not immediately generate an observable modification.\textsuperscript{[13]} This is why changes in regulation network are frequently unobtrusive. The redundancy in regulations hides the transient changes induced in the network, at least as long as the environmental conditions do not affect this latter level of regulation. However, a strong perturbation in many physiological and developmental factors is observed during this period as soon as plants are exposed to suboptimal conditions.

The concept of critical periods is well known in physics and in chemistry, in which nonlinear processes now play a central role. Ignoring such a reality in biology invites contradictory conclusions about the effects of stress and plant response to it. It is unlikely that the concept of critical period will be restricted to interorgan relationships and response to stress at the whole plant level. The concept is probably useful in a series of phenomena, from...
molecular interactions in the cell[14] to species interactions in a biocoenosis.[15]

INTRODUCTION

The plant genome is in a dynamic state, and a range of environmental pressures can stimulate particular alterations. Flax, a bifunctional crop that can be grown for fiber (flax) or oil (linseed), is particularly susceptible to such alterations. Some varieties undergo heritable genomic and phenotypic alterations during a single generation’s growth in certain particular destabilizing environments. These genomic changes have been shown to occur in all types of sequences, including highly repetitive tandem arrays, intermediately repetitive dispersed regions, and low-copy number sequences. The genomic changes have been shown to occur during the vegetative growth, resulting in chimeric plants. However, in all the cases that have been characterized to date, the genomic alterations have become homozygous in the plant prior to the reproductive structures being differentiated. Therefore, because flax is essentially a self-fertilizing plant, all the progeny for a particular plant are identical, but could be different from the parent plant. More important, all the progeny from a series of plants grown under the same environment are identical, illustrating that there is reproducibility in response to such environmental pressures. Some of the genomic alterations appear to be adaptive to the conditions under which they are induced, but in every case these possible adaptive changes are part of a large number of genomic regions that are disrupted under any given growth conditions.

Why Study Flax?

The initial observations of flax were made by Durrant when he investigated the previously reported effect of growth conditions on the vigor of the flax seed. A series of flax varieties were grown under a variety of conditions and allowed to self. The seed was collected and grown under a uniform set of conditions. The progeny for the different parental treatments had different phenotypes. For one particular variety, Stormont Cirrus, a small number of the treatments (including an imbalance of nutrients or particular temperature regimes) resulted in lines that bred true for the altered phenotypes, irrespective of subsequent growth conditions, although the phenotype resulting from most of the environmental conditions depended on growth conditions in the immediately preceding generation. These stably altered types were termed genotrophs, and the progenitor line termed plastic, Pl. These lines were, for all intents and purposes, different genetic types. The lines differed in many characteristics, including plant height. The plant height characteristic illustrates a number of points relating to the induced changes. As seen in Fig. 1, all the plants derived from a single set of growth conditions are uniform, but different from those grown under a different set of conditions. This height difference is observed irrespective of the growth conditions, and is mainly due to a change in the length of the first few internodes.

WHAT CHANGES OCCUR IN RESPONSE TO NUTRITIONAL AND TEMPERATURE STRESS?

Although much remains to be learned about the induction process in flax, four aspects are established. First, Stormont Cirrus is a predominantly self-fertilizing plant because anther dehiscence and pollination usually occur during flower opening. Second, nearly all of the seeds planted grow under the inducing conditions and can contribute to the next generation. Thus it is extremely unlikely that any form of selection, in the conventional sense, from a heterogeneous population of plants, is the causative agent for the observed change. Third, all of the self-fertilized progeny from all the individuals growing in a specific environment are identical, but different from all the progeny of individuals grown in a different environment. Fourth, the induction of the changes has been repeated with Pl, resulting in the appearance of similar phenotypic, biochemical, and molecular changes.

The described phenotypic variations among the genotrophs (height, weight, capsule hair, septa number, and isozyme mobility) are but the tip of the iceberg when compared to the extent of variation seen at the DNA level. With regard to nuclear DNA, the extreme types differ by 15% of their total DNA as determined by Feulgen
staining. This level of variation has been confirmed by the characterization of nuclear DNA by renaturation analysis, the cloning of families of repetitive sequences, the detailed characterization of the families of large (25S+18S) and small (5S) ribosomal RNA genes, RAPD analysis, and representational difference analysis. A notable characteristic of all the DNA comparisons is the specificity of the changes between Pl and the genotrophs. Independent induction events have resulted in identical new structures at many loci, confirming the precise nature of the induced changes. For example, specific polymorphisms have been repeatedly generated in independently induced genotrophs in subsets of the 5SRNA gene family, and specific RAPD polymorphisms have repeatedly appeared. Within the flax genome, therefore, there exists a set of regions that are particularly labile and able to be altered in response to environmental stresses. Such a labile subset that responds during in vitro regeneration in barley has also been described. An important observation is that the availability of these sites is dependent on the physiological status of the plant. Therefore, the array of genomic alterations that occurs in response to any particular set of conditions will depend on the particular stress conditions applied.

**WHEN IN DEVELOPMENT DO THE INDUCED CHANGES OCCUR?**

Two of the genomic changes that have been characterized in detail are variations in ribosomal RNA gene number and a 5.8 kb insertion sequence named LIS-1. The latter is present in a number of genotrophs and in many other flax and linseed varieties. Both of these sequences have been followed during the growth of plants under inducing conditions, particularly under reduced mineral nutrition, and have shown similar responses. The variation in ribosomal RNA gene number occurred during vegetative growth of Pl under inducing conditions, and was complete before the plants flowered. Similarly, the appearance of LIS-1 was followed in Pl while growing under three different nutrient regimes; leaves were sampled as the plants grew. All three conditions resulted in the appearance of LIS-1 in the DNA extracted from leaves. Under two of these regimes, however, all the plants became homozygous for the insertion, and the inserted site was transmitted to all the progeny, whereas under the third regime, none of the progeny had LIS-1 inserted.

**CONTROL OF THE GENERATION OF VARIATION**

Within the flax genome there exists a set of regions that are particularly labile and able to be altered in response to environmental stresses. These sites vary frequently, and are therefore difficult to map by conventional genetic crosses, as they can vary in the generation in which they are scored. However, some flax varieties do not respond by destabilizing the genome when grown under these conditions. One of the crosses examined confirms that the loci controlling the response can also segregate, and can therefore be mapped and isolated. An understanding of the control of these genomic changes in flax will guide the search for similar mechanisms in other plants.

**ARE THESE RAPID CHANGES ADAPTIVE?**

What are the circumstances wherein such reorganization would confer a substantial advantage in an evolutionary context? First, it would need to be an inducible system so that when the organism is surviving well in a given environment there is no continuous generation of variation (although one could question whether any environment is really optimum). Ideally, the variation would only be
generated when the organism senses the need. The way in which such a sensory mechanism may work is not clear at present. Second, the regions of the genome that are targeted for restructuring need to be delineated. It appears unlikely that restructuring can occur at random. Random mutagenesis will mainly generate deleterious events rather than useful variation. Therefore, to have an advantageous mechanism, it is important to delineate regions of the genome that will be especially labile. The identification of these regions will be essential in understanding how the genomic reorganizations result in phenotypic variation. Third, the breeding system of the organism is also likely to be important. In the case of an inbreeding species, there will be little variation left when growth occurs in a favorable environment over an extended period. Thus, in such a circumstance, a significant change in the environment is likely to be disastrous, unless a mechanism is present by which either variation can be introduced or maintained. Therefore, it is likely that evolutionary selection will favor the presence of a controlled plasticity in those inbreeding species that have survived the slings and arrows of outrageous environments.

A question arises over the adaptive nature of any of these nuclear changes. In flax, it is clear that not all of the changes can be adaptive, as many of the variants are common to lines that have different phenotypes. The obligatory appearance of LIS-1 after some treatments, however, versus its complete absence after others indicates that it is likely to be of importance in the selection of that specific genomic variation under those conditions. It is therefore either one of the regions that confers adaptive advantage under those conditions, or is closely linked to the advantageous change. Because other heritable epigenetic changes such as imprinting can act at a distance from their chromosomal site, a characterization of the genomic context of this element may prove to be instructive.

**CONCLUSION**

These results in flax are the first demonstration that a series of genomic locations are labile and specifically responsive to particular environmental conditions. Within the set of variants, a particular combination of changes can be selected that are adaptive in those conditions. Under these circumstances the environment acts as an inducer of variation and then as the subsequent selective agent among the variants generated to genetically alter all or the majority of the population. These results have clear evolutionary implications for any organism in which the germline is not set aside very early in development, as this mechanism can give rise to a coordinated set of variations under particular environmental conditions. The understanding of the control of these genomic changes in flax will be invaluable in the search for and understanding of the same processes in other species.

INTRODUCTION

Whole plants and cultured plant cells have the capacity of increasing their tolerance to stress. This may occur through reversible, preexisting switches, as in phosphate starvation that induces a series of new enzymes. Other examples are the facultative halophytes that modify their carbon-fixing mechanism from C3 to CAM under drought or saline stress. Other examples of overcoming stress are through irreversible changes, such as the effects on flux of imbalanced mineral nutrition or particular temperature regimes (discovered by Durrant in the late 1950s and further studied by Cullis); the discovery by McClintock that stress may cause nonrandom reorganization of the genome and chromosome aberrations in corn; and adaptation of sorghum to NaCl concentrations that are lethal for the unadapted plant. At the cultured plant cell level it has been shown that tobacco cells can be adapted to grow in 500 mM NaCl, and McCoy showed that exposure of cultured alfalfa cells to salt stress enhances dramatically the frequency of both chromosome aberrations and altered isozymes. This article discusses mechanisms of irreversible changes induced by stress.

THE PLANT’S DEVELOPMENTAL TRAJECTORY

The physiological response of a plant is modified as a function of its development. This change as a function of time is the developmental trajectory of the plant, often referred to as phasic development. Moreover, there are limited time periods—developmental windows—during which a plant’s response is temporarily modified.[1] The unfolding of internal developmental programs and external signals affect the developmental trajectory, which reflects the genetic makeup of the plant as well as its environmental history. All cells contain two types of information—the genetic information and the epigenetic system that is affected by environmental and developmental cues.[2]

During the unfolding of the developmental trajectory the plant undergoes continuous modulation in its phytohormonal balance as well as in its sensitivity (its response) to phytohormones; in protein, posttranslational modifications such as phosphorylation/dephosphorylation; in histone, modifications such as acetylation, methylation, phosphorylation, and probably DNA methylation. At the same time there is a reorganization of the genome that entails amplification and deletion of DNA (including A+T- and G+C-rich DNA) and DNA inversion.[3,4] All these changes are mechanisms that modulate genome expression during development.

STRESS-RESPONSE MECHANISMS

Somaclonal Variations

Following plant regeneration from cultured cells, protein modifications and aberrations in chromosomes and DNA sequences are seen. These changes have been called somaclonal variations because they arise within clones of somatic cells. Modified phenotypes are sometimes, but not always, heritable.[5] The number of aberrations increases with the length of time cells are maintained in culture and with intensity of stress conditions.[5,6] Recurrence of similar types of somaclonal variations in cultured cells, which are sometimes similar to known heritable mutations in whole plants,[5] indicates that there are hot spots for these changes; the phenomenon appears to be nonrandom. Observation of bridges at mitotic and meiotic anaphase suggests that a mechanism called breakage–fusion–bridge cycle (BFB) could be responsible for some of these mutations.[5,7] The appearance of new isozymes and restriction fragment length polymorphism (RFLP) and rapid amplification of polymorphic DNA (RAPD) techniques are sensitive methods that reveal slight modifications in DNA sequences due to somaclonal variations.[5,6] The mechanisms inducing somaclonal variations are unknown; however, several causes have been suggested, including imbalanced nutrient concentrations, phytohormones, leakage of cellular constituents, DNA amplification/deletion, chromosome breakage (including BFB), transposon movement, and 5-methylcytosine deamination.[5]

Changes in Concentration of Phytohormone and Other Molecules Under Stress

Under stress, the concentration of abscisic acid and ethylene increases while the concentration of auxins,
cytokinins, and gibberellins decreases. Other molecules such as polyamines, brassinosteroid, methyl jasmonate/jasmonic acid, and salicylic acid are sometimes produced. Reactive oxygen species (ROS) such as superoxide radical, hydroxyl radical, and hydrogen peroxide are also produced under stress. See the contribution of A. Levine in this volume for the consequence of ROS on genome organization.

### Genome Modifications Under Stress

For many plant species the haploid genome size (1C-value), in picograms (pg) or base pairs, has been reported in the literature.\[9,10\] 1 pg = 965\times10^6 bases. 1C-values for flowering plants range from <0.2 pg in Arabidopsis thaliana to 127.4 pg in Fritillaria assyriaca.\[10\] From these values, the genome size varies by more than 600-fold, even though these plants express more or less similar genes, suggesting that the difference in chromatin content is due to noncoding DNA. Reasons for such differences could be changes in ploidy level, repetitive DNA such as tandemly repeated sequences that are grouped in one or a few sites (e.g., rDNA; satellite DNA that can be either A+T- or G+C-rich), or dispersed repeated sequences that are spread throughout the genome (e.g., amplification of transposable elements).

Growth of the inbred flax variety Stormont Cirrus in an inducing environment (such as imbalanced mineral nutrition or specific temperatures) causes stable and genetically altered plants after a single generation.\[11\] The phenomenon is reproducible. Following similar treatment, identical changes are observed in plant height and weight at maturity and in the number of hairs on the false septa of the seed capsules. This is not due to selection because >90% of the seeds germinate and undergo the same changes. These phenotypic changes are accompanied by alterations in the number of repeats of repetitive DNA of both the tandem rDNA and in families of dispersed repeated sequences. These phenotypic/genotypic modifications are maintained for all generations tested.

The discovery that stress results in chromosome aberrations in the whole corn plant\[7\] and in cultured alfalfa cells\[6\] shows that stress modifies genome organization. This is also demonstrated by somaclonal variations\[5,6\] because, for a plant cell, being cultured constitutes a stress. Adaptation of whole sorghum plants to NaCl\[11\] is passed on to progenies for all generations tested (Amzali personal communication). This suggests the inclusion of a genetic effect. Development of cultured cells from regenerated plants obtained from NaCl-adapted tobacco cells\[12\] yields already adapted cells (Watad personal communication), also suggesting that this adaptation is a genetic effect. The course of accommodation to stress entails modifications in both genome organization and in the process of modulation of genome expression. Another example of genome modification under stress has been shown for cold hardening.\[13\]

### Range of Stress-Response Process

Not all flax or sorghum varieties undergo the phenotype/genotype modifications described here; these changes are specific properties of particular varieties. Although the processes occurring in flax and sorghum seem similar, they are not identical. In flax all the plants submitted to an inducing condition undergo the same modification, whereas in sorghum there is an increase in the variability of parameters within the population (e.g., shoot height, shoot dry weight) following the adaptation treatment,\[14\] indicating that each individual plant within the population undergoes its own stress–response pathway.

There is a wide range of plants’ mechanisms of accommodation to stress—from reversible preexisting switches (e.g., phosphate starvation,\[15\] facultative halophytes\[16\]), to irreversible preexisting switches (e.g., flax\[11\]), to the irreversible elaboration within a population of new patterns of modulations of genome expression (e.g., sorghum\[11\]).

### Nuclear Architecture

Using in situ radioactive DNA hybridization, the organization of parental chromosomes in plant hybrids is shown to occupy distinct, nonrandom, positions. Throughout the cell cycle, parental genomes are maintained in different domains, including during interphase (Ref. 9, Refs. 67,88 in Ref. 9). Moreover, using fluorescent in situ hybridization (FISH) on animal cells, it has been confirmed that the folding of DNA in chromatin is highly specific.\[17\] It seems probable that nuclear organization may affect or be affected by gene expression.\[17\]

### CONCLUSION

The mechanisms of accommodation of plants to stress include all the mechanisms functioning during the plant’s developmental trajectory, including changes in phytohormonal balance and sensitivity to phytohormones; protein posttranslational modification; DNA reorganization through amplification, deletion, and inversion; histone modification; DNA methylation; and movement of transposons. All these changes modulate genome organization and expression. The nucleus is a dynamic, plastic, highly organized organelle that, as described by McClintock, is capable of reorganizing itself to overcome adverse conditions. Although transformation is a very interesting and useful tool in plant research, for agriculture it is more
advantageous to allow crop plants to modify their genomes by themselves because they are better equipped than humans to do so.

INTRODUCTION

Because plants are sessile organisms, their growth and development greatly depend on abiotic and biotic environmental factors. Plants have developed efficient mechanisms for sensing changes in growth conditions and for induction of adaptive processes in order to cope with various kinds of environmental stress. Plants are ultimate harvesters of sunlight, and maintenance of a functional photosynthetic apparatus is fundamental for plant survival under unfavorable conditions. Light is the main environmental regulator in modifying the structure and function of plant photosystems. Other abiotic factors, e.g., extreme temperatures and oxidative stress, also induce changes in the photosynthetic machinery, but their action depends on light. Structural and functional modifications of Photosystem I and Photosystem II under abiotic stress conditions will be discussed in this article, with emphasis on protein phosphorylation, changes in subunit and pigment composition, and induction of protecting compounds.

PHOTOSYSTEM II

Photosystem II (PSII) functions as a light-driven water-plastoquinone-oxidoreductase in plant thylakoid membranes. PSII is composed of more than 25 proteins, including the subunits of the reaction center responsible for primary photochemistry, the oxygen evolving complex, and the polypeptides of chlorophyll a/b antenna.[1] Functional PSII exists as a dimeric complex. In nature, plants experience continual short-term and long-term fluctuations in light intensity. PSII is a main regulated unit in the light reactions, and is thus also a primary target for modifications induced by environmental factors. The best-documented modifications of PSII are associated with photoinhibition of photosynthesis, including both the induction of photoprotective mechanisms and oxidative damage to PSII. Some of the changes are rapidly reversible on a time scale ranging from seconds to hours under transient changes of irradiance, whereas long-term exposure to new light conditions causes stable adjustments of the complex. Protein phosphorylation and changes in pigment composition belong to the reversible modifications occurring in PSII under variable environmental conditions. On the other hand, protein synthesis is required to cope with stress-induced photodamage to PSII, including the replacement of the oxidized protein with the new copy (see below) as well as the stimulation of the expression of protective proteins called ELIPs (early light inducible proteins) and a PSII subunit of 22 kDa (psbs).

Light-induced Protein Phosphorylation in Thylakoid Membranes

Light induces phosphorylation of a number of PSII proteins in thylakoid membranes. Four PSII core proteins—D1 and D2 reaction center proteins, 43-kDA chlorophyll a-binding protein (CP43), and the psbH gene product (psbH protein)—undergo reversible phosphorylation in thylakoid membranes.[2] The PSII antenna consists of six pigment-binding proteins designated Lhcb1 to Lhcb6, from which three (Lhcb1, Lhcb2, and Lhcb4) have been shown to become reversibly phosphorylated in light-dark transitions.[1,2,3] Light regulates this phosphorylation via the redox state of electron carriers between PSII and PSI.[2] Reduction of plastoquinone activates serine/threonine protein kinase(s) that phosphorylate the PSII core phosphoproteins and Lhcb4 protein,[3] whereas both the reduction of plastoquinone and subsequent binding of plastoquinol to the Qo site of the cytochrome b6:f complex are required to initiate the phosphorylation of Lhcb1 and 2 proteins.[1,2,3] Moreover, the kinase that phosphorylates the Lhcb1 and 2 proteins is specifically inhibited in the presence of thiol reductants.[3] Significantly, thylakoid membranes contain several membrane-bound protein kinases with specific regulation mechanisms and at least partial substrate specificity for PSII phosphoproteins. Decreasing redox potential in the chloroplast, e.g., by shifting plants into darkness, induces the dephosphorylation of PSII phosphoproteins via protein phosphatases.[2] Both soluble and membrane-bound phosphatases capable of dephosphorylating PSII phosphoproteins have been found in chloroplast. However, these enzymes are still poorly characterized.

Previously, the reversible phosphorylation of PSII proteins was assumed to be coupled to light stress of the chloroplast through prevention of the imbalance between
excitation rates of the photosystems under fluctuations in light intensity, and via protection of PSII from photoinhibition in high light (discussed later). This scheme presumes that an exposure to high light would induce the phosphorylation of PSII proteins. However, screening of the environmental conditions activating the phosphorylation of PSII proteins in vivo has indicated that maximal phosphorylation of the PSII core proteins occurs at light conditions prevailing during growth of plants without any evident symptoms of light stress. This maximal phosphorylation level, corresponding to 70–80% of PSII complexes with phosphorylated PSII core proteins, is maintained under conditions with redox potential equivalent to or higher than observed at growth light conditions. Moreover, the antenna proteins Lhcb1 and 2 are maximally phosphorylated only at low redox potential in the chloroplast, e.g., after a shift of the plant to a light intensity lower than experienced during growth, while high light strongly inhibits phosphorylation of these proteins. Only the phosphorylation of the Lhcb4 protein seems to be specifically stress-stimulated.

What are the physiological implications for the PSII complex modified by protein phosphorylation? A number of functional roles have been suggested for PSII core protein phosphorylation. Chlorophyll fluorescence and low temperature electron paramagnetic resonance (EPR) measurements have demonstrated that phosphorylation of D1, D2, and CP43 proteins does not influence the electron transfer capacity in PSII. Stabilization of a dimeric form of PSII—and direct protection of PSII from photoinhibition—have also been linked to the phosphorylation of PSII core proteins, but discrepancies in the experimental results mean that these hypotheses should still be questioned. A number of experimental data, however, support the hypothesis that phosphorylation of the PSII core proteins regulates the PSI photoinhibition repair cycle by controlling the timing and location of proteolytic degradation of the photodamaged D1 protein in thylakoid membranes. This regulation prevents a collapse and total proteolysis of the subunits of photodamaged PSII complex, especially under the stress conditions that cause deterioration of protein synthesis, e.g., low temperature combined with illumination of plant.

Phosphorylation of Lhcb1 and 2 proteins has been proposed to induce state transition that modulates energy distribution between PSII and photosystem I (PSI) in plant thylakoid membranes. Phosphorylation of these proteins results in partial dissociation of the phosphorylated Lhcb1 and 2 proteins from PSII, and subsequent association of these proteins with PSI. Originally, the state transition was thought to protect PSI from photoactivation by reducing the antenna size of PSII, and thereby the excitation of PSII. However, this function is not supported by the finding that excessive light intensity strongly inhibits the phosphorylation of these proteins. It has been proposed that Lhcb1 and 2 protein phosphorylation regulates the synthesis of Lhcb proteins during the long-term acclimation of plants to various light intensities. A putative role of this phosphorylation in the relay of signals between chloroplast and nucleus is based on the distinct positive correlation between the phosphorylation level of Lhcb1 and 2 proteins and the expression of Lhcb genes.

Phosphorylation of Lhcb4 protein has been attributed to the protection of PSII complex against photoinhibition, especially in chilling-sensitive plants at low temperatures. This protection may be attained by altered distribution of excitation energy between PSII and its antenna after phosphorylation of Lhcb4 protein.

The Xanthophyll Cycle and Photoprotection of Chloroplasts

Besides the photochemistry in thylakoid photosystems, light reactions also generate reactive intermediates and oxygen species that have a potential to damage the photosynthetic machinery, especially in excess light. To prevent their detrimental effect, plants have evolved a number of protection mechanisms—including antioxidant systems and processes for thermal dissipation of light energy.

The extent of the thermal dissipation in PSII can be measured as a quenching of chlorophyll fluorescence in PSII. The energy-dependent component (qE) of non-photochemical quenching (NPQ) depends on the amount and composition of xanthophyll pigment in membranes, as well as the acidification stage of the thylakoid lumen. The xanthophyll cycle is a universal pigment-conversion mechanism in plants that is involved in the dissipation of excess light energy to heat in thylakoid membranes. In higher plants under light stress, zeaxanthin is formed from violaxanthin via antheraxanthin in the reactions catalyzed by violaxanthin de-epoxidase (VDE), which is activated through acidification of the thylakoid lumen. The cycle is reversible under low light conditions, resulting in the regeneration of violaxanthin via the action of zeaxanthin epoxidase. Xanthophylls bind to chlorophyll a/b binding proteins of both PSII and PSI antennae, but this cyclic conversion of pigments has been proposed to occur in a free form of the molecule, resulting in the reorganization of xanthophyll pigments in Lhcb proteins. Studies with Arabidopsis mutants with reduced levels of VDE have shown the involvement of zeaxanthin in thermal dissipation of excess light energy. However, the exact mechanism for this energy dissipation is still obscure. According to the direct model, chlorophyll transfers excitation energy to zeaxanthin, which dissipates it as heat. Alternatively, the production of zeaxanthin may stimulate the proton-dependent structural changes in Lhcb proteins (aggregation, protein–protein interactions) resulting in
the formation of dissipation centers in specific antenna complexes.\textsuperscript{[5]}

Recently, a new component involved in dissipation of thermal energy in PSII has been established. \( q_E \) was absent in a \( psbS \)-deletion mutant in Arabidopsis.\textsuperscript{[7]} \( psbS \) protein is a component of PSII with homology to chlorophyll a/b binding proteins. However, the chlorophyll-binding domains are not conserved, which excludes the possible role of \( psbS \) protein in light harvesting. Transgenic \textit{Arabidopsis} plants overexpressing \( psbS \) gene had significantly increased \( q_E \) and enhanced resistance to PSII photoinhibition.\textsuperscript{[8]} Moreover, low-temperature stress increases the expression of \( psbS \) gene in illuminated potato leaves. These results strongly support the role of \( q_E \) in photoprotection and also the hypothesis that the key function of \( psbS \) protein is in the induction of energy-dependent thermal dissipation. The putative function of this protein is in sensing the luminal acidification, which induces a conformational modification of \( psbS \) protein and/or of Lhcb proteins, finally resulting in the stabilization of the dissipation centers in PSII.\textsuperscript{[5]}

**Photoinhibition of Photosystem II**

Despite the photoprotection mechanisms discussed above, irreversible inhibition of photosynthesis occurs in illuminated plants. Both PSII and PSI can be targets of oxygen-dependent photodamage of the reaction center, but under different environmental conditions. Photodamage to PSII can be detected at all physiological light intensities; moreover, the absorption of light in excess of the capacity to utilize it in plants leads to the accumulation of inactive PSII complexes in thylakoid membranes.\textsuperscript{[3]} PSI photoinhibition is induced especially at low temperatures under moderate light intensities.\textsuperscript{[9]}

Irreversible photoinactivation of PSII ultimately results in oxidative damage to the reaction center protein D1 of PSII. To restore the activity of PSII, the photodamaged D1 protein is degraded by proteolysis and substituted by a newly synthesized D1 protein.\textsuperscript{[3]} Strict coordination of the degradation and synthesis of the D1 protein is necessary to prevent loss of other polypeptides in this multisubunit complex, which would lead to total collapse of the complex and thus to more severe damage to the photosynthetic machinery. This coordination is attained via regulation of the turnover of D1 protein by phosphorylation of PSII core proteins.\textsuperscript{[3]} The key feature in this regulation is that the phosphorylated form of the photodamaged D1 protein is not susceptible to proteolytic degradation. Inactivation of PSII takes place in grana lamellae, whereas the co-translational incorporation of the new D1 copy is spatially conceivable only in stroma-exposed thylakoid membranes (Fig. 1). Phosphorylation of PSII core proteins stabilizes the partially disassembled inactive PSII complex upon migration from the grana region to the stroma-exposed

---

![Fig. 1](image1.png)  
**Fig. 1** Phosphorylation of the PSII core proteins and photoinhibition repair cycle of Photosystem II in higher plant thylakoid membranes. (From Ref. 3.)
membranes of thylakoids, in which repair of the complex is induced by dephosphorylation of PSII core proteins, followed by degradation of photodamaged D1 and synthesis of a new copy of protein (Fig. 1).

PHOTOINHIBITION OF PHOTOSYSTEM I

Photosystem I is a light-driven plastocyanin-ferredoxin oxidoreductase involved in the production of NADPH in photosynthetic light reactions. The enzyme complex is composed of 14 subunits, from which the PsA, PsB, and PsC proteins bind the electron carriers of PSI.[1] PsA-PsB heterodimer functions also as a core antenna by binding approximately 90 chlorophyll a molecules and 10–15 β-carotenes per reaction center. The chlorophyll a/b-binding proteins of PSI antenna are encoded by four Lhca genes designated Lhca1 to Lhca4.[1]

PSI is not regarded as a rate-limiting component of the light reactions; thus, the dynamic and regulatory aspect of PSI has been investigated less extensively. Low temperature combined with light, however, inhibits PSI activity specifically—both in chilling-sensitive and tolerant plant species.[9] This oxygen-dependent PSI inactivation results in the degradation of the psaA-psaB heterodimer of the PSI reaction center, but a loss of some extrinsic PSI proteins has also been reported.[9] The unique features of PSI photoinhibition are that: 1) bleaching of chlorophyll is observed after return of plants to the growth temperature; 2) degradation of PSI proteins occurs several days after exposure to low temperature; 3) the recovery is much slower than in PSII photoinhibition; and 4) it can ultimately result in a definitive decrease in the amount of PSI complexes in leaves. This more severe photoinhibition of PSI under specific environmental conditions may be due to lack of control over the repair of photodamaged PSI reaction center proteins, compared to the mechanism that has evolved for PSII complexes.

CONCLUSION

Light is a key element in modifications of the photosynthetic apparatus that are induced by various abiotic stress factors. The molecular aspects of changes in the structure and function of photosystems are studied mainly by combining light with one of the environmental variables at a time. In nature, stresses can appear contemporaneously, compounding the symptoms and allowing the development of new modifications in plants. In the near future, the establishment of new technologies such as DNA microarray analysis, proteomics, and metabolomics will vastly increase our knowledge of the dynamic aspects of the photosynthetic apparatus, even under the complex environmental conditions that exist in nature.

EARLY LIGHT-INDUCED PROTEINS: A STRESS PROTEIN FAMILY IN THYLAKOID MEMBRANES

Originally, the early light-induced proteins (ELIPs) were found upon greening of etiolated seedlings. Expression of these proteins was induced very early after the shift of seedlings to light, although they were not present in mature leaves under ambient growth conditions. However, it was observed later that the expression of these proteins is induced under several different conditions of stress, including light, cold, and salt stress, as well as during nutrient deprivation and desiccation.[10] ELIPs and chlorophyll a/b-binding proteins have sequence similarity, but only binding of chlorophyll a and lutein has been detected in purified proteins.[10] It is generally agreed that these proteins are not involved in energy transfer in photosynthesis. They are localized to the stroma-exposed membranes of thylakoids, probably in close vicinity to PSII complexes, but the direct interaction of ELIPs with the photosystems is still obscure. Furthermore, a number of protective roles of ELIPs under stress conditions has been suggested,[10] although the exact function of these proteins remains to be elucidated. One tempting hypothesis is that ELIPs might bind pigments released from the photosystems during the reorganization of complexes (e.g., photoinhibition, the xanthophyll cycle) under different stress conditions.

INTRODUCTION

Phosphatidic acid (PA) is emerging as the most important lipid second messenger in plants. It is formed within minutes in response to a wide array of stress conditions, including ethylene, abscisic acid (ABA), cold, Nod factor, pathogen-derived elicitors, wounding, drought, salt, and hypoosmotic stress. PA and the enzymes that form and metabolize this molecule seem to play a key role in plant stress signaling.

FORMATION OF PA

Phospholipids maintain the integrity of biological membranes around cells and their organelles. Relatively new is the awareness that several of them play a crucial role in signal transduction. One of the latest additions to this field is the lipid second messenger PA, a minor lipid that occurs in different cellular membranes. When a plant cell is subjected to stress, two different phospholipases can be activated to hydrolyze structural membrane lipids, resulting in the production of PA. Phospholipase D (PLD) hydrolyzes phosphatidylcholine (PC) or phosphatidylethanolamine (PE) to release PA and a free headgroup (choline or ethanolamine), while phospholipase C (PLC) hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_{2}) to generate inositol 1,4,5-trisphosphate (IP_{3}) and diacylglycerol (DAG), which is immediately phosphorylated by DAG kinase (DGK) to produce PA. The increase is transient because PA is rapidly converted to diacylglycerol pyrophosphate (DGPP) by PA kinase (Fig. 1).

Phospholipase D

Several genes encoding PLDs have been cloned from plants. In Arabidopsis thaliana, there are twelve members that have been grouped into five classes. Individual isoforms have different expression patterns and different biochemical properties. A recent discovery is the association of a PLD with microtubuli, where it could mediate cytoskeletal rearrangements, which are known to occur in response to several stress treatments. When PLD hydrolyzes its substrate, it can use primary alcohols instead of water as an acceptor for the phosphatidyl group (transphosphatidylation). Thus, in the presence of n-butanol, phosphatidylbutanol is formed. This characteristic has been used to measure in vivo PLD activity, but also to inhibit PA production and to distinguish PLD-generated PA from PLC-generated PA.

Phospholipase C

In the Arabidopsis genome, there are nine PLCs, of which four have been cloned and characterized. The PA they generate together with DGK can be distinguished from that generated by PLD by a differential ^{32}P-labeling protocol and by using specific PLC inhibitors.

THE ROLE OF PHOSPHATIDIC ACID IN STRESS SIGNALING

PA formation has been linked to biotic and abiotic stress treatments, suggesting it is a general stress signal. In support, inhibiting or silencing PLD in plants reduces stress responses, while exogenous application of PA induces stress responses. Some of the best characterised PA responses are discussed here.

ABA and Osmotic Stress

The phytohormone ABA is involved in aging, seed development, germination, and the responses to cold and water stress. It induces the formation of PA in stomatal guard cells and aleurone cells. Osmotic stress, in the form of salt or drought, also increases the level of PA. Both PLC and PLD pathways are activated in response to osmotic stress and ABA. Moreover, in plants in which PLD expression is suppressed, ethylene and ABA-induced senescence, as well as other ABA- and osmotic stress-related responses,
are reduced. Interestingly, exogenously applied PA mimics ABA action in guard cells; it inhibits ion channel activity and induces stomatal closure.\textsuperscript{[5]}

**Defense Against Pathogens**

A well-studied mechanism of plant defense against pathogens are pathogen-derived elicitors, which activate the plant’s defense responses. Several elicitors, such as xylanase, chitin tetraose, flagellin, and the *Cladosporium fulvum* race-specific elicitor Avr4, induce PA formation within minutes.\textsuperscript{[8]} Interestingly, Nod factors that are signal molecules of symbiotic *Rhizobium* bacteria also induce the formation of PA in leguminous plants. Wounding a plant triggers PA accumulation, as well, both locally and systemically.\textsuperscript{[5]}

The PA produced in response to pathogen elicitors and Nod factor is mainly due to PLC activation. Blocking PLC enzyme activity inhibits activation of several defense responses, including the formation of reactive oxygen species. Conversely, exogenously applied PA induces an oxidative burst and triggers a MAP kinase pathway, showing that PA is involved in the early response to pathogen attack. PLD is involved in the response to some elicitors and to wounding. When rice is infected by *Xanthomonas oryzae*, PLD is recruited to the site of infection on the plasma membrane. Silencing PLD reduces the wound-induced accumulation of jasmonic acid.\textsuperscript{[5,8]}

**PA ACTION AND SPECIFICITY**

It is becoming clear that PA plays a major role in cell signaling even though little is known about its working mechanism. Presumably, the formation of PA creates docking sites in the membrane to which specific proteins bind (Fig. 2). Membrane recruitment then leads to activation, either directly by PA or indirectly by other proteins.\textsuperscript{[8]} In addition, PA’s shape and negative charge could affect membrane properties, promoting curvature and vesicle formation.
Another major question regards the specificity of the PA signal. Since a variety of environmental conditions induce the formation of PA, one must ask how response specificity is maintained. Of course, first there will be a level of tissue and developmental information that determines the final response to environmental cues, the hard wiring of the cell. And every stress treatment will activate both specific and general signaling pathways. Thus, PA may represent a general, multifunctional stress signal that integrates different pathways, similar to the action of calcium and MAP kinases.[9]

PA Targets

Several mammalian proteins that directly interact with PA have been identified. These so-called PA targets are involved in various cellular processes, such as mitogenic signaling, vesicular trafficking, and the oxidative burst, and include protein kinases and phosphatases, lipid kinases, cAMP-phosphodiesterases, small G-proteins, mTOR, and NADPH oxidase. PA-binding regions in some of them have been identified by deletion studies, but their sequences do not show significant homology to each other.[10]

Few PA targets have been identified in plants. PA affects ion-channel and MAP-kinase activity in vivo, but it is not known whether this is due to direct binding. Phosphoinositide-dependent protein kinase 1 (PDK1) binds PA and a calcium-dependent protein kinase (CDPK) is activated by PA in vitro but clearly more targets must be identified to distinguish a general PA-binding domain and to understand how PA signals stress (Fig. 1).

CONCLUSION AND PERSPECTIVES

PA is a secondary messenger that has all the qualities of a general stress-signaling molecule in plants. It is formed in response to stress conditions and it induces downstream responses typically related to stress, while prevention of PA formation reduces these responses. One of the major challenges will be to find the molecular targets for PA.

Other main goals in this field are to find the upstream regulators of the PA-generating enzymes, and to localize PA in the living cell, using fusion constructs of PA-binding domains with green fluorescent protein. Over-expression of a PA-binding domain can be used to inhibit PA signaling, and knocking out individual PLC and PLD isoforms will establish their contribution to the PA signal under different conditions. These type of approaches will help us to understand what the role of PA is in stress and other responses.

INTRODUCTION

Plant growth is greatly affected by water deficit. Plants respond and adapt to dehydration in order to survive under drought stress by the induction of various biochemical and physiological responses. Various genes are induced in response to drought at the transcriptional level. Their gene products are thought to function in response to drought and in tolerance to drought. It is important to analyze functions of stress-inducible genes not only to understand higher plants’ molecular mechanisms of stress response but also to improve the stress tolerance of transgenic plants. The expression and functions of stress-inducible genes have been studied at the molecular level. Complex mechanisms seem to be involved in gene expression and signal transduction in response to drought stress. This article describes recent progress on cis- and trans-acting factors involved in drought-inducible gene expression.

EXPRESSION PROFILES OF DROUGHT-INDUCIBLE GENES USING MICROARRAY TECHNOLOGY

Microarray technology has been developed extensively and has become a powerful tool for the global analysis of expression profiles of many genes. This microarray technology allows the large-scale comparative analysis of gene expression under various stress conditions. Recently, many drought-inducible genes have been identified in Arabidopsis. Microarray analysis has revealed the existence of strong cross talk between drought and high salinity responses, and moderate cross talk between drought and cold stress responses. Various kinds of genes with different functions are involved in stress tolerance and stress response. Among the stress-inducible genes, many transcription factor genes have been identified, suggesting that various transcriptional regulatory machineries function in drought-inducible gene expression.

ABA-DEPENDENT AND ABA-INDEPENDENT GENE EXPRESSION IN RESPONSE TO DROUGHT STRESS

Dehydration triggers the production of abscisic acid (ABA), which in turn, not only causes stomata closure but also induces various genes. As shown in Fig. 1, it is hypothesized that at least four independent signal pathways function in the activation of stress-inducible genes under dehydration conditions: Two are ABA-dependent (pathways I and II) and two are ABA-independent (pathways III and IV). One of the ABA-dependent pathways requires protein biosynthesis (pathway I). ABA-independent regulatory systems are thought to function in the early process of drought-stress signaling before the accumulation of ABA.

ABA-INDEPENDENT GENE EXPRESSION

One of the ABA-independent pathways of drought-stress response overlaps with that of cold-stress response (pathway IV). Promoter analysis of drought-inducible rd29A gene reveals that a cis-acting element including A/GCCGAC, named the Dehydration Responsive Element (DRE) and C-Repeat (CRT), is essential for regulation of the induction of rd29A under drought, low-temperature, and high-salt stress conditions in an ABA-independent pathway. All the DRE/CRT-binding proteins (DREBs and CBFs) contain a conserved DNA-binding motif (AP2/ERF motif). These five cDNA clones that encode DRE/CRT-binding proteins are classified into two groups, DREB1/CBF and DREB2. Expression of the DREB1A (CBF3) gene and its two homologues (DREB1B = CBF1, DREB1C = CBF2) is induced by low-temperature stress, whereas expression of the DREB2A gene and its single homologue (DREB2B) was induced by dehydration. These results indicate that two independent families of DREB proteins, DREB1/CBF and DREB2, function as trans-acting factors in two separate signal transduction pathways under low temperature and dehydration conditions.
respectively.[5] Overproduction of the DREB1A/CBF3 and CBF1/DREB1B cDNAs in transgenic plants significantly improves stress tolerance to drought and freezing.[5–7] Microarray analysis identifies many genes with various functions as DREB/CBF target genes.[8,9]

Several drought-inducible genes including erd1 do not respond to either cold or ABA treatment, which suggests the existence of an additional ABA-independent pathway in dehydration stress response (pathway III). Promoter analysis of these genes will give us more information on pathway III.

**ABA-DEPENDENT GENE EXPRESSION**

Endogenous ABA increases significantly under drought and high salinity conditions. Many drought-inducible genes are upregulated by exogenous ABA treatment. In one of the ABA-dependent pathways (Fig. 1, pathway II), drought-inducible genes do not require protein biosynthesis for their expression. These dehydration-inducible genes contain potential ABA-responsive elements (ABREs; PyACGTGGC) in their promoter regions. ABRE functions as a cis-acting DNA element involved in ABA-regulated gene expression. ABRE was first identified in wheat Em and rice rab genes, and its DNA-binding protein EmBP1 was shown to encode a bZIP protein.[2] Two ABREs function in the ABA-dependent gene expression of rd29B. Two ABRE-binding proteins (AREB1 and AREB2) are involved in ABA-responsive gene expression and contain the bZIP structure.[10] AREB1 and AREB2 genes are induced by drought; their gene products seem to be activated by phosphorylation. AREB1 and AREB2 function downstream from abi1/abi2 and era1 in ABA signal transduction pathways. Similar ABRE-binding proteins have been identified and named as ABFs that function in stress tolerance.[11,12]

Biosynthesis of novel protein factors is necessary for the expression of ABA-inducible genes in one of the ABA-dependent pathways (pathway I). The induction of an Arabidopsis drought-inducible gene, rd22, is mediated by ABA, and requires protein biosynthesis for its ABA-dependent expression. MYC and MYB recognition sequences are essential for the ABA- and drought-responsive expression of rd22. Transcription factors—MYB (ATMYB2) and MYC (rd22BP1)—are thought to function in the regulation of slowly stress-inducible genes after the production of ABA-inducible transcription factors (pathway I).[13]

Many drought- and ABA-inducible genes encoding various transcription factors have been reported. These contain conserved DNA-binding motifs, such as zinc finger, homeo box, and WRKY motif. Among them, ATHB6 (containing the homeodomain) functions as a negative regulator downstream of ABI1 protein phosphatase in the ABA signal transduction pathway.[14]

**GENETIC ANALYSIS OF DROUGHT-STRESS SIGNAL TRANSDUCTION**

Genetic analysis of Arabidopsis mutants with the rd29A promoter::luciferase transgene reveals complex cross talk among signaling pathways in drought-, salt-, and
cold-stress responses, and suggests that stress-signaling pathways, (including ABA-independent and ABA-dependent pathways) are not completely independent. Recently, many genes have been identified using map-based cloning, some of which encode putative transcription factors. Genetic analysis of these mutants is thought to provide more information on drought-stress signal transduction.

CONCLUSION

Many genes are induced by drought stress. Analyses of stress-inducible gene expression have revealed the presence of multiple signal-transduction pathways between the perception of drought-stress signal and gene expression. At least four different transcription systems function in the regulation of dehydration-inducible genes; two are ABA-responsive and two are ABA-independent. This explains the complex stress response observed after the exposure of plants to drought stress. Some genes are rapidly induced by drought stress, whereas others are slowly induced after the accumulation of endogenous ABA. Genetic analysis of Arabidopsis mutants also suggests complex signaling pathways in drought-, salt-, and cold-stress responses. Functional genomics has become a powerful approach to elucidate complex stress-signaling cascades.

INTRODUCTION

Unlike algae, terrestrial plants do not benefit from a well-buffered environment provided by large water bodies. The atmosphere cannot as efficiently attenuate sudden changes in the environment, and land plants—notably desert plants—are exposed to a plethora of combined environmental stresses: heat-shock, water loss, excess light, accumulation of oxygen radicals, osmotic shock, freezing, mechanical stress, etc. Unlike animals, plants have limited motility and cannot seek shelter to escape damage from daily and seasonal variations in the environment. One powerful defense mechanism involves a network of molecular chaperones, which can prevent stress-induced protein aggregation and actively scavenge and refold stable aggregates into functional native proteins.

PROTEIN AGGREGATES AND ACQUIRED STRESS RESISTANCE

Because proteins maintain a delicate equilibrium between structural rigidity and functional flexibility, external stresses may cause them to lose their native conformation and seek alternatively stable inactive structures, called aggregates. Because of their insoluble hydrophobic nature, aggregates may interfere with membrane functions such as photosynthesis and occupy vital cellular space. Some protein aggregates from mammals, the amyloids and prions, cause neural degeneration. Deleterious properties of stress-induced protein aggregates in plants are unknown. Yet the fact that high levels of heat shock proteins (Hsps), which prevent stress-induced aggregation and regulate plant development, are induced in stressed plants strongly suggests that Hsps act to minimize interference with vital cellular processes by protein aggregates.

Most organisms, including plants, have evolved defense mechanisms that can react to various mild doses of stress and build up responses in anticipation of more extreme stresses to come.\(^1\) Although more economical than maintaining various defense mechanisms at all times, acquired resistance is transient by nature. Hence, an abrupt, unannounced stress may not allow enough time to establish proper defense mechanisms, while as time passes, previously induced defense mechanisms may subside and lose their ability to withstand a renewed challenge.

MAJOR MOLECULAR CHAPERONES IN PLANTS AND THEIR ROLES UNDER HEAT STRESS

The effect of heat shock has been extensively studied as a paradigm of other types of environmental stresses. Nearly all organisms, including plants, arrest protein synthesis during mild, nonlethal heat shock, except for a subset of proteins termed heat shock proteins (Hsps), which are produced in large amounts. Induction of heat shock genes in response to heat stress is mediated by transcriptional activator proteins (HSF) that trimerize and bind to cis-regulatory promoter elements (HSEs) conserved in all eukaryotes.\(^2\) Molecular chaperones, many of which are Hsps, belong to several classes of proteins initially classified according to their molecular weight: Hsp110, Hsp100, Hsp90, Hsp70, Hsp60, and small Hsps. Hsp chaperones have also constitutively expressed cognates (Hsc), which are sequence-related and carry housekeeping chaperone functions under nonstressed conditions.

Hsp70

Hsp70 is a highly conserved molecular chaperone present in all living organisms (with the exception of some archeabacteria). In the model plant Arabidopsis thaliana, about 14 highly homologous (>45% identity) Hsp70 members are expressed constitutively (Hsc70), or in a stress-dependent manner (Hsp70). The encoded proteins are localized to the cytosol, endoplasmic reticulum (ER), mitochondria, and chloroplasts (Table 1). In addition, there are four members of the Hsp110 family, which is sequence-related to the Hsp70 family. In neuronal cells, Hsp110 prevents stress-induced apoptosis and may regulate the Hsp70/40 chaperone system.

Hsp70 (DnaK in E. coli) is composed of a 40-kDa ATPase domain and a 30-kDa protein-binding domain. DnaK collaborates with two co-chaperones, DnaJ (Hsp40)
and GrpE. DnaJ is thought to bind locally to hydrophobic regions in loops of misfolded proteins. DnaJ-bound loops are then transferred to the protein-binding pocket of DnaK, triggering ATP hydrolysis. Release of the bound polypeptide from DnaK requires GrpE, which accelerates nucleotide exchange in DnaK. Reiteration of such local binding/release events likely leads to a gradual disentanglement of the polypeptides from the aggregates and correct refolding of the polypeptide.[3] Hsp70 collaborates with other molecular chaperones and can be considered as the core element of the chaperone network in the cell, toward which are funneled various forms of misfolded proteins for disaggregation (Fig. 1).

The Arabidopsis genome expresses a plethora of Hsp40-like proteins, which because of their DnaJ-like domains are suspected to interact with the various members of Hsp70s in the cell and drive specific chaperone reactions. Plant genomes contain several prokaryoticlike GrpE genes, likely in the chloroplasts and mitochondria. Hip (Hsp70 interacting protein) proteins have also been identified in plants and might regulate Hsp70 activity, as in animals, by stabilizing Hsp70 in an ADP-conformation with high affinity for the polypeptidic substrate.[4] In Arabidopsis and various other organisms, Hsp70 seems to act as a negative feedback regulator of HSF activity. Indeed, when excess Hsp70 (and other Hsps) is synthesized under heat stress, its interaction with heat shock factors could repress transcription of heat shock genes.[5]

Hsp100

Hsp100 proteins from prokaryotes and eukaryotes are also termed Clp (for caseinolytic protease) because the first member described was E.coli ClpA/P protease, which can hydrolyze casein in vitro. Hsp100/Clp proteins are divided in two major classes: ClpA/B/C/D containing two ATP-binding domains, and ClpM/N/X/Y containing only one ATP-binding domain.[6] Most ClpB proteins are Hsps, which, together with Hsp70, carry the solubilization and refolding of large protein aggregates.[3]

Several Hsp100s have been isolated in different plant species. They are found in the cytosol, in mitochondria, and in chloroplasts. In plants, expression of Hsp100 is developmentally regulated.[7] Arabidopsis Hsp100s present four ClpB-like, three ClpA-like, and eight related proteins whose functions cannot be predicted by sequence analysis (Table 2). Plant ClpB-like Hsp101 (At1g74310) plays a crucial role in the acquisition of thermotolerance, but it is dispensable for development and germination in

![Functional hierarchy of the chaperone network](www.dekker.com)
the absence of stress.[7] It will be interesting to address the protein-refolding and/or proteolytic functions of the many Clp-like genes in *Arabidopsis* and their contribution to various stress resistances.

### Small Hsps

In most prokaryotes and eukaryotes, various stresses induce low-molecular-weight (small) 10–30 kDa heat shock proteins (sHsps), which all share a conserved C-terminal domain similar to mammalian \( \alpha \)-crystallin. They often form loose, hollowed, oligomeric structures comprising 9 to 32 subunits.
